A. GODLEY,
Under Secretary of State for India

INDIA OFFICE,
November, 1902.

REPORT.

The present Report on Sanitary Measures in India during the year 1900 is prepared for presentation to Parliament. It contains chapters on the health of the European and Native troops, on the health of prisoners in jails, and on the health of the general population ; it also contains chapters on vaccination, on medical institutions, including medical schools and lunatic asylums, and a chapter on sanitary works. Appended to the Report are abstracts of reports by the three principal Sanitary Commissioners in India, and memoranda by the Army Sanitary Commission in England reviewing the several Sanitary Reports for India.

I.—EUROPEAN ARMY.

Sickness and mortality in 1900.

There was less sickness among the European troops on service in India in 1900 than in the previous year, but the decrease was somewhat overweighed by an increase in mortality and invaliding. On an average strength of 60,553, the admissions into hospital were in the ratio of 1,143 per 1,000, against 1,149 in 1899, the daily sick-rate fell from 73 to 72, and the death-rate rose from 12·75 to 14·62. The invaliding ratio (33) was higher by 1 per 1,000, so that the total loss by death and invaliding was equal to 48 per 1,000, an increase of 3 per 1,000 on the previous year.

The following statement shows the relative extent of sickness and mortality among European troops in the four Commands during 1900 and the previous year :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.				
			Admissions.	Daily Sick.	Deaths.	Invaliding.	Total Loss.
Bengal	1900	18,956	1,075	70	13·40	33	46
	1899	21,278	1,191	81	13·82	36	50
Punjab	1900	16,562	1,085	65	12·62	27	40
	1899	18,080	1,085	62	14·82	24	39
Madras	1900	9,984	1,268	82	16·53	46	63
	1899	12,876	1,259	82	10·10	39	49
Bombay ...	1900	15,051	1,211	75	17·08	33	50
	1899	15,462	1,073	67	11·06	29	40
INDIA ...	1900	60,553	1,143	72	14·62	33	48
	1899	67,697	1,149	73	12·75	32	45

It will be seen from the above statement that Madras was the most unhealthy of the four Commands, Bombay coming next, and that both compare unfavourably with the previous year. In regard to mortality, there was an improvement in the Punjab and the Bengal Commands, their death-rates having fallen from 14·82 and 13·82 per 1,000 respectively to 12·62 and 13·40.

The chief causes of sickness in the whole European Army were, as in the year 1899, intermittent fever and venereal diseases, the former yielding a ratio of 308 per 1,000 against 235 in 1899, and the latter 298 per 1,000 against 313. More than a half (53 per cent.) of the total sickness resulted from these two causes. Enteric fever, as usual, was the chief cause of mortality, the death-rate from it being 4·77, which however is an improvement on 5·14, the ratio of the previous year. One-third of the total deaths was due to this cause.

Groups of stations.—The following table shows the sickness and mortality among the European troops according to groups :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,047	1,273	79	22·92
Burma Inland	1,723	1,672	101	15·67
Bengal and Orissa	2,153	1,356	75	19·97
Gangetic Plain and Chutia-Nagpur	5,748	1,057	70	12·87
Upper Sub-Himalayan	11,105	1,244	74	15·40
North-Western Frontier, Indus Valley, and North-Western Rajputana.	4,628	1,173	66	12·53
South-Eastern Rajputana, Central India, and Gujarat.	6,003	1,396	89	20·82
Deccan	9,358	1,160	74	16·99
Western Coast	1,491	781	53	14·76
Southern India	2,069	1,286	71	11·60
Hill Stations	8,874	726	53	8·45
Hill Convalescent Depôts and Sanitaria ...	3,247	1,127	79	14·78

Of the above 12 groups, seven returned a higher daily sick-rate than that for the European Army as a whole, and in eight groups the death-rate was greater. The most unhealthy groups, judged by the daily sick-rate, were Burma Inland and Central India, with daily sick-rates of 101 and 89 per 1,000 respectively.

Of the stations with a strength of over 1,000, the highest death-rates were those of Secunderabad (25·18), Meerut (18·73), Mhow (18·53), Poona (17·45), and Lucknow (17·16). In all these stations, except Lucknow, the mortality was higher than in 1899.

Cholera.—The mortality from cholera, which in 1899 had been the lowest on record, only one fatal case having been recorded, rose to 88 out of 107 cases. Nearly a fourth of the deaths occurred among the troops stationed at Secunderabad where the disease attacked all the corps in barracks except the Artillery.

Small-pox.—Among the whole of the European troops in India there were during the year under notice 36 cases of small-pox with three deaths. In the previous year there were 14 cases and one death.

Fevers.—From intermittent fever the admissions to hospital among the European troops in 1900 were in the ratio of 308 per 1,000 of strength, against 235 in the previous year. The death-rate was also higher, viz., 0·66 per 1,000, against 0·28 in 1899.

From enteric fever the admissions fell from 1,392 or 20·6 per 1,000 of strength to 970 or 16·0, and the deaths from 348 or 5·14 per 1,000 to 289 or 4·77. The decrease is attributed chiefly to "the almost complete absence of drafts from England and the freedom from field service." Of the four Commands, Bombay recorded the highest mortality under this head, viz., 6·71, followed by Madras 4·71, Punjab 4·35, and Bengal 3·64. Among the larger stations with an average strength of over 1,000, Quetta returned a death-rate from this fever of 11·40, Peshawar 10·06, Secunderabad 9·83, Meerut 7·49, Lucknow 7·35, Poona 7·35, Belgam 5·99, Rawalpindi 4·40, Agra 4·13, and Umballa 4·08. As usual, young and unacclimatised soldiers were the chief sufferers; among those from 20 to 25 years of age the death-rate was 6·85 per 1,000 against 7·55 in 1899, while among men between 25 and 30, and from 30 to 35, the mortality was 3·65 and 2·01 per 1,000 respectively. Among men of less than one year's residence in India the death-rate from this fever was 7·95 per 1,000, among men between one and two years 9·20, and among men between five and ten years' service 3·15 per 1,000. Of the total 289 deaths from enteric fever, 61 per cent. occurred among men between the ages of 20–25, and 31 per cent. among men of less than two years' residence in India.

Bowel Complaints.—The admissions from dysentery and diarrhœa among the European troops were in the ratio of 44 per 1,000 of strength, or 1 per 1,000 more than in 1899. The mortality from dysentery was in the ratio of 0·86 against 0·65 in the previous year, and from diarrhœa 0·05 against *nil.* Dysentery was most prevalent, as usual, in the Bengal-Orissa group, but it was more prevalent in the Madras and Bombay Commands than in that of Bengal.

Abscess of the Liver.—From abscess of the liver there were 94 deaths, yielding a ratio of 1·57 per 1,000 of strength, against 85 or 1·26 in 1899.

Plague.—There were six cases of plague among the European troops, and one death, against seven cases and two deaths in 1899.

Venereal Diseases.—Venereal diseases ranked second in the list of causes of admission to hospital, and first in the causes of invaliding. They were the cause of 26 per cent. of the total sickness during 1900, and of over 18 per cent. of the invaliding of the European Army of India. The admission-rate from venereal diseases per 1,000 of strength was 298·1 against 313·4 in 1899, being 224 per 1,000 less than the maximum rate (522·3) recorded in 1895. "So far," the Army Sanitary Commission remark, "the measures adopted during recent years with the object of lessening the disastrous effects of this scourge have been productive of marked benefit; but the returns show that there is ample room for further reduction of the numbers rendered inefficient by it." The Madras Command returned the highest rate, viz., 354·4 per 1,000 against 397·8 in 1899. Bombay came next with a ratio of 327·0 against 273·6, Bengal with 299·9 against 364·0, and the Punjab with 235·8 against 226·7. The number of men constantly sick in hospital from these diseases was 1,630, against 1,851 in the previous year; and the average stay of a case in hospital was about 33 days. The deaths from these diseases numbered 14, and the invalidings 380, against 14 and 440 respectively in 1899.

Invaliding.—The loss to the whole army by invaliding during 1900 amounted to 2,026 men, equal to 33·46 per 1,000, against 2,142 or 31·64 in 1899. The proportion of invalids to strength was highest in the Madras Command (45·77), followed by Bengal (32·97), Bombay (32·82), and Punjab (27·17). As regards the influence of age and length of residence in India upon invaliding, 52 per cent. of the total number invalided were under 25 years of age, against 59 in 1899, while 33 per cent. against 38 were of less than two years' service, and 72 per cent. against 81 were of less than five years' service. In the European Army of India as a whole 69 per cent. of the total strength had seen less than five years' service.

II.—NATIVE ARMY.

Sickness and Mortality in 1900.—The health of the Native Army of India was also not so good as in 1899.

The ratios of sickness and mortality among Native troops in the five Commands during 1900 and the previous year are given in the following table :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.		
			Admissions.	Daily Sick.	Deaths.
Bengal	1900	26,582	717	31	10·46
	1899	26,820	716	29	10·03
Punjab	1900	42,311	796	28	14·72
	1899	44,224	731	27	12·48
Madras	1900	20,407	690	30	12·69
	1899	23,255	672	30	9·03
Bombay	1900	24,908	957	35	18·71
	1899	26,657	699	26	10·69
Hyderabad Contingent	1900	6,260	561	22	12·62
	1899	6,556	430	15	6·86
INDIA	1900	123,463	785	30	14·04
	1899	128,529	705	28	10·70

Of the five Commands, Bombay was the most unhealthy in 1900, returning a death-rate of 18·71 per 1,000, against 10·69 in the previous year ; the Punjab returned the next highest mortality of 14·72. Pneumonia was very prevalent in these two Commands, and the death-rates from it were 4·38 and 4·30 per 1,000 respectively.

The chief cause of sickness in the Native Army was ague, which caused 41 per cent. of the total admissions. Among the diseases from which the admissions to hospital were higher than in 1899 were cholera, enteric fever, ague, dysentery, diarrhœa, small-pox, and venereal diseases ; while from influenza and respiratory diseases there was a decrease in the admissions. From cholera the admission-rate rose from 1 per 1,000 of average strength in 1899 to 5·2, and from venereal diseases the admission-rate rose from 34·1 to 42·5, as compared with 298·1 per 1,000 among European troops. There were 9 deaths and 129 invalidings from venereal disease, against 14 deaths and 380 invalidings among European troops.

Pneumonia and cholera were the chief causes of death in the Native Army, and no less than 46 per cent. of the total deaths were due to them. The death-rate from pneumonia was 3·32 per 1,000 of average strength, against 3·86 in 1899. From this disease the mortality among the Native soldiers was more than eight times as great as that among European troops (0·40 per 1,000). Fevers of all kinds were the cause of 16 per cent. of the total deaths, against 39 per cent. among the European troops. From ague, remittent and simple continued fevers, the deaths among the Native troops were in the ratio of 2·09 per 1,000, while among the European troops the proportion was 0·86. On the other hand, the death-rate from enteric fever among the Native troops was only 0·15 per 1,000, as compared with 4·77 among the European troops.

From cholera there were 390 deaths in the Native Army, equal to 3·16 per 1,000 of strength, as compared with 68 or 0·53 in 1899.

During 1900 there were 56 cases of plague among the Native troops with 29 deaths, against 76 cases and 45 deaths in 1899.

Groups of stations.—The following statement gives the principal statistics of the Native Army, arranged in geographical groups, for 1900 :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,406	785	31	14·22
Burma, Inland	4,123	1,038	34	4·12
Assam	1,498	714	38	7·34
Bengal and Orissa	2,565	1,157	45	14·42
Gangetic Plain and Chutia-Nagpur	5,658	716	31	7·78
Upper Sub-Himalayan	15,326	676	26	8·55
North-Western Frontier, Indus Valley, and North-Western Rajputana.	15,861	928	32	21·37
South-Eastern Rajputana, Central India, and Gujarat.	11,169	1,017	38	21·04
Deccan	17,670	717	28	13·75
Western Coast	2,435	702	32	25·05
Southern India	6,764	652	33	14·04
Hill Stations	19,885	836	34	15·39

In ten of the 12 groups the daily sick-rate was higher than that for the whole Native Army, and in six the mortality was greater. The highest mortality was recorded by the Western Coast group, viz., 25·05, of which dysentery and diarrhœa contributed 6·57. In 1899 this group returned a death-rate of 9·98.

Of the large stations with a strength of over 1,000, the following recorded the highest death-rates :—Kohat 49·23, Bombay 39·71, Edwardesabad 31·27, Secunderabad 27·78, and Abbottabad 22·02. All these five stations returned high death-rates from cholera.

III.—GENERAL POPULATION.

The year 1900 was not a healthy one. The weather was hot and rather dry, with an approximately normal rainfall. Famine prevailed in several provinces, and all the chief diseases were unusually active. On the whole the health of the general population was bad. The returns of the year having been tabulated before the recent census, the birth and death-rates are calculated on the census figures of 1891.

Vital statistics.

Births were registered throughout all the 10 provinces in India in 1900, and the birth-rates varied between 41·1 and 26·2 per 1,000 of population under registration. All the provinces, except Madras, Lower Burma and Coorg, returned a lower birth-rate than in 1899, the falling off being attributed chiefly to scarcity and high prices and epidemic disease. The highest rates were recorded in the Punjab, the North-Western Provinces and Oudh, Bengal, Lower Burma and Assam, their respective rates being 41·1, 40·3, 38·6, 38·3, and 34·9. In the remaining provinces the birth-rates ranged between 31·9 in the Central Provinces and 26·2 in Coorg. The birth-rates exceeded the death-rates in five out of the ten provinces, the excess per 1,000 varying between 11·0 in Lower Burma and 2·0 in Bengal. The recorded deaths rose from 6,418,409 or 29·95 per 1,000 of registered population in 1899 to 8,322,584 or 38·1. Compared with 1899 the increase in mortality in 1900 was due to the greater prevalence of all the chief diseases. In all the provinces except Assam and the North-Western Provinces and Oudh the mortality was higher than in the previous year. Cholera was exceptionally prevalent during 1900, and the deaths rose from 169,236 to 804,378, the highest number on record. The increase was spread over all the provinces, but the chief sufferers were Bombay, the Central Provinces, Berar, Bengal and Assam, whose death-rates from cholera were 8·71, 7·14, 6·4, 4·86, and 4·51 respectively. The rise in the deaths from fevers by three-quarters of a million (774,691) was spread over all the provinces, except North Western Provinces and Oudh, Lower Burma and Assam. Plague was not so prevalent as in the two previous years, and the deaths fell from 139,000 in 1899 to 92,807. The decrease was principally in Bombay. Assam and Coorg continued to remain unaffected.

The deaths from the chief diseases and from all causes in the several provinces were as follow :—

	Cholera.		Small-pox.		Fevers.		Dysentery and Diarrhœa.		Deaths from all Causes.		
	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000 of Population under registration.

Bengal.

The year was an unhealthy one in Bengal, and prices of food grains were high. The number of births registered in the province fell from 3,053,178 or 42·96 per 1,000 of population in 1899 to 2,749,582 or 38·68, the latter being made up of district rates varying from 49·19 in Noakhali and 46·83 in Tippera to 28·53 in Hooghly and 15·8 in Calcutta. Of the 46 districts there was a decrease of births in all except six, the greatest decrease being in Palamau, where the ratio was 15·51 per 1,000 below that of the

previous year. This district recorded the highest birth-rate in 1899 (53·28). Eighteen districts returned a birth-rate of over 40 and 26 of over 30 per 1,000, the highest, as already stated, being 49·19 in Noakhali. Calcutta returned the lowest birth-rate, and, as usual, compared unfavourably in this respect with other towns, its birth-rate being lower by 11·85 than the average of other urban areas.

Eleven towns returned a birth-rate in excess of 40 per 1,000, while 107 rural areas recorded rates of over 45 per 1,000. These figures are considerably below those of the previous year.

The total number of deaths registered during the year under notice was 2,603,736 or 36·63 per 1,000, as compared with 2,218,243 or 31·21 in 1899. There was thus an excess of births over deaths of only 145,846 or 2 per 1,000, against nearly 12 per 1,000 in the previous year. The district death-rates ranged from 55·66 in Purnea to 21·28 in Manbhum. In both urban and rural areas there was a marked increase in mortality, the rate of the former having risen from 33·10 to 43·46, and in the latter from 31·11 to 36·28.

From all the principal diseases the mortality was higher than in 1899. Cholera prevailed with greater severity, and the death-rate was the highest on record. The deaths rose from 107,678 or 1·51 per 1,000 to 345,878 or 4·86. No district entirely escaped the disease, and it attacked 33,142 villages against 17,217 in the previous year. Of individual districts the mortality was highest in Purnea (23·77 per 1,000), followed by Champaran (11·74), and in 19 others the rates ranged from 8·48 to 40 per 1,000. The excessive prevalence of the disease is attributed to the early cessation of the rains in the previous year and the lateness of the monsoon in 1900. As regards the seasonal incidence of the disease, the mortality was highest in the second quarter of the year and lowest in the first.

A large number of anti-cholera inoculations were performed during the year with remarkable success. Out of 873 coolie emigrants who were inoculated in the Purulia coolie depôt in Goalundo and were subsequently exposed to the contagion of the epidemic, only two were attacked ; while out of 1,527 uninoculated coolies 32 or 2·09 per cent. got cholera.

Deaths from small-pox rose from 13,116 or 0·18 per 1,000 in 1899 to 20,620 or 0·29 in 1900. The disease was present in all the districts, and compared with the previous year the mortality was higher in 30, lower in 13, and equal in three districts. The only districts in which it can be said to have prevailed in an epidemic form are Cuttack, Puri, Calcutta, and Palamau, with death-rates of 3·98, 2·46, 1·48 and 1·33 respectively. In no other district did the death-rate under this head reach 1 per 1,000.

Nearly 66 per cent. of the total deaths were recorded under fever. The number of deaths reported to have occurred under this head during the year was 1,703,804 or 23·97 per 1,000 of population, against 1,607,279 or 22·61 in 1899. Out of the 46 districts, 22 recorded a higher fever mortality than the provincial rate, twelve registering a rate of over 30 per 1,000. Dinajpur ranked first with a rate of 40·41, followed by Jalpaiguri 39·0, Faridpur 36·66, and Malda 36·14. Notwithstanding the high fever mortality, there was no corresponding increase in the sale of quinine, but, on the contrary, a slight decrease. In the previous year there was an increase of 8,423 on the number of packets sold in 1898.

Dysentery and diarrhœa prevailed with increasing severity throughout the year, 64,664 deaths having been registered, equal to 0·91 per 1,000 of population, against 41,334 or 0·58 in the previous year. The incidence of these diseases was higher than that of the preceding year in 43 districts out of 46. Darjeeling, which in 1899 occupied the third place, with a ratio of 3·11 per 1,000, headed the list with more than double that rate, viz., 6·33, followed by Calcutta 6·05, Patna 5·90, Howrah 4·96, Puri 4·85, and Cuttack 3·18.

Plague was present in the province throughout the year, and the total mortality recorded from it was 38,412, against 3,264 in 1899. The increase was greatest in the districts of Patna, Saran, and Gaya, the first of these recording 22,574 deaths. It is reported that disinfection of huts, houses, and clothing was largely resorted to in plague infected areas, and that in many instances people were induced to vacate their houses and camp out on new sites in the open—in some places this was done spontaneously.

In the municipality of Calcutta the birth-rate fell from 16·14 in 1899 to 12·7. The registered deaths numbered 36,709 or 43·5 per 1,000 of population, against 25,823 or 37·8 in the previous year. There was an increase in mortality under all the chief death causes. Cholera deaths rose from 990 to 2,754, small-pox deaths from 62 to 1,010, and deaths ascribed to fever from 7,173 or 10·5 per 1,000 to 7,642 or 11·21. From plague 8,354 deaths were registered in the city, against 2,681 in 1899.

North-Western Provinces and Oudh.

In the North-Western Provinces and Oudh the year 1900 was a healthy one, the birth-rate being considerably above the average, though lower than the exceptionally high rate of the previous year; and the death-rate was below the quinquennial mean. During the year 1,892,169 births were recorded, being equal to 40·34 per 1,000, against 2,255,627 or 48·09 in the previous year, which was the highest on record, the rate previously highest being 43·77 in 1884. Of the total 48 districts, 25 showed a birth-rate above and 23 below the average of the provinces. Bulandshahr again headed the districts with a birth-rate of 52·89, followed by Etah 52·34, Budaun 49·82, Farukhabad 49·28, Muzaffarnagar 48·57, and Bareilly 48·20. The birth-rate in municipalities was 41·26, against 47·24 in the previous year, and was made up of extremes ranging from 60·82 in Kandhla to 16·51 in Mussoorie.

The number of deaths registered was 1,460,139 or 31·13 per 1,000 of population, against 1,556,824 or 33·19 in 1899. The provincial death-rate, which was made up of district rates ranging from 45·40 in Sultanpur to 22·37 in Banda, was exceeded in 22 districts. The urban death-rate was 42·13, against 39·04 in 1899. Out of 104 municipalities, 41 recorded more deaths than births. Registration was again tested by local authorities, and the results disclosed an omission of 2·31 per cent. on 287,245 births, and 1·71 on 225,245 deaths; and in cases tested by the Vaccination Department, the omitted percentages were 0·51 of births and 0·31 of deaths.

Cholera was more prevalent than in 1899, and the mortality was the highest recorded since 1894. The total deaths from the disease numbered 84,960 or 1·81 per 1,000, against 8,142 or 0·17 in 1899. Sultanpur recorded the highest district rate of 15·96, followed by Bareilly 5·24, Rae Bareli 4·46, Ballia 4·26, and in five other districts the rates exceeded 3 per 1,000. Two districts, Almora and Hamirpur, were entirely free from the disease, and no outbreak occurred at any of the large fairs. Out of a total of 107,239 villages 7,465 were visited by cholera. The mortality was lightest in February (15 deaths), and heaviest in June (14,846). In noting the absence of epidemic disease at the great fairs, the Sanitary Commissioner, Lieutenant-Colonel Thomson, I.M.S., observes: "In past years these large gatherings were constantly the origin of widespread sickness and death. It is difficult to attribute the immunity from such outbreaks in recent years to anything but improved and systematic sanitary measures."

The absence of small-pox was even more marked than in 1899, the mortality having fallen from 2,096 or 0·04 to 1,410 or 0·03, which is the lowest rate recorded since 1871, when trustworthy registration began. No high death-rates were reported in the districts, of which four escaped the disease altogether. Aligarh headed the districts with a death-rate of 0·45, but except in this area the number of deaths did not exceed 100 in any district.

The mortality from fever in 1900 was lower than in the previous year, the number of deaths having fallen from 1,245,260 or 26·55 per 1,000 to 1,106,030 or 23·58. Among the districts, Bulandshahr came first with a fever death-rate of 38·51, followed by Muttra 36·40, Muzaffarnagar 33·53, Mainpuri 32·75, Meerut 32·73, Aligarh 32·03, Naini Tal 31·60, and 16 other districts recorded ratios above the provincial rate. The mortality reached its maximum in October, and the minimum was in February. In addition to the sale of quinine at a low price by postal agency, the experiment of selling it through landholders and other non-official agency was tried in four districts, and seemed likely to be successful.

The deaths from dysentery and diarrhœa rose from 27,206 or 0·58 per 1,000 in 1899 to 30,652 or 0·65. Among districts, Garhwal again recorded the highest ratio, viz., 7·68, followed by Almora 4·31, Dehra Dun 3·47, Benares 2·34, and Jhansi 2·16, the first four standing in the same order as in the previous year.

There was very little plague in the provinces during the year, only 135 deaths having occurred. In the previous year only seven deaths were reported in the provinces.

Punjab

The year 1900 in the Punjab was unhealthy. The province suffered severely from famine, and cholera and malarial fever were very prevalent. The number of births registered was 843,970 or 41·1 per 1,000 of population, as compared with 994,001 or 48·4 in 1899. Notwithstanding this great decrease, the birth-rate was higher than that of any other province in India, and was made up of district ratios ranging from 77·7 in Jhang to 21·7 in Simla. In 14 districts the provincial birth-rate was exceeded. The decrease in the birth-rate was very considerable in the famine affected districts of Hissar, Rohtak, Gurgaon, Karnal, Jhelum, Shahpur, and Ferozepore. The provincial birth-rate was lower than the death-rate by 6 per 1,000 of population; in one district (Hissar) the excess of deaths over births was nearly 72 per 1,000; and in eight other districts the increase of deaths over births ranged between 44 and 10 per 1,000.

From all causes 980,211 deaths were registered, giving a death-rate of 47·69, against 607,725 or 29·57 in 1899. The highest district rates were reported from Hissar 96·4, Ferozepore 86·8, Karnal 73·7, Rohtak 68·0, and in 11 other districts the death-rates ranged from 61·5 to 40·8.

The province suffered severely from cholera during the year, and the total number of deaths registered from the disease was 28,260 or 1·37 per 1,000 of population, against only 33 deaths in 1899. More than half the deaths were contributed by the famine affected districts of Hissar, Rohtak, Karnal, Ferozepore, and Lahore, and the first of these districts contributed no less than 23 per cent. of the total cholera deaths. One district (Simla) was entirely free from the disease, and in another (Kangra) only one death was recorded. Only 634 cholera deaths occurred during the first three months of the year. In April there were 1,888 fatal cases, and the maximum number of 9,711 was registered in July. In each of the following five months there was a decrease in the mortality, December recording only 17 deaths. The disease was confined to 2,551 villages out of a total of 38,548.

Small-pox was more than usually prevalent, causing a mortality of 10,425 and a death-rate of 0·51, against 5,149 or 0·25 in 1899. All the districts were affected, but the disease was severe only in five., viz., Gurgaon with a death-rate of 2·45, Hissar 1·68, Peshawar 1·48, Montgomery 1·22, and Jhang 1·02. Of the total 10,425 deaths from this disease, 2,728 occurred among children under one year, and 6,457 among children over one and under ten years of age.

The mortality from fevers was greatly in excess of that recorded in 1899, and was equal to 70 per cent. of total deaths from all causes. The deaths numbered 685,895 or 33·37 per 1,000, against 388,689 or 18·57 in 1899. The provincial rate was exceeded by nine out of the total 31 districts, the highest being Hissar 70·02, Ferozepore 69·36. Karnal 55·39, and Rohtak 51·23. In five other districts the provincial death-rate from fevers was exceeded.

From dysentery and diarrhœa the deaths numbered 25,913 or 1·26 per 1,000 against 15,747 or 0·77 in 1899. The increase was general throughout the province; it occurred with few exceptions in every district. It was most marked in the famine affected districts, particularly Hissar, which recorded a death-rate from these diseases of 3·64 against an average of 1·06 for the five previous years.

Plague was present in the province during the year, and 495 deaths were recorded, against 255 in the previous year. Only three districts were affected, viz., Jullundur, Hoshiarpur, and Gurdaspur, but the disease was again chiefly confined to Jullundur.

Central Provinces.

The year 1900 was the most unhealthy one the Central Provinces have experienced for twenty years, except the famine year of 1897. Pestilence and famine had to be encountered, and resulted in a low birth-rate and an unusually high death-rate. A total of 335,436 births was registered, being equal to 31·87 per 1,000 of population, against 497,419 or 47·35 in 1899. The falling off was general, the decrease varying from 1,851 in Burhanpur to 27,321 in Raipur; and in only four districts was there an excess of births over deaths. By districts the birth-rates ranged from 43·74 in Nimar to 25·55 in Bilaspur. The provincial birth-rate was exceeded in fifteen districts.

The deaths during the year numbered 608,691 or 57·82 per 1,000, against 291,054 or 27·65 in 1899 and 658,822 in 1897. "In face of the undoubted fact," the Sanitary Commissioner states "that in 1897 the actual physical conditions were much less severe in extent and degree than in 1900 the only explanation I can offer of the comparatively low death-rate on the latter occasion is that it was due to relief measures having been then instituted at an earlier date, before the general health of the people had much deteriorated, and to their having been subsequently carried out on a more liberal scale and under better organization and supervision." The provincial death-rate was exceeded in nine districts, with ratios varying between 110·82 in Nimar and 61·21 in Bhandara. With the exception of Mandla district there was a rise in the mortality in every other part of the provinces.

Cholera was unusually severe and extensive, 75,112 deaths having been recorded or 7·14 per 1,000 of population, against only 76 deaths in 1899. The year commenced with 162 deaths in January, and the disease increased in fatality until June, when the deaths went up to 23,027. Then followed a decline, and only 5 deaths occurred in November, when the epidemic finally disappeared.

Small-pox was much more prevalent than in the previous year, and the deaths rose from 1,511 or 0·14 per 1,000 in 1899 to 8,021 or 0·76. The disease affected every district but one (Mandla), but only in four districts did the death-rate exceed 1 per 1,000, Sambalpur ranking highest with 3·52. Of the total small-pox deaths 2,026 occurred among infants and 2,671 among children between one and 10 years of age.

Fever claimed more victims than all the other diseases put together, the deaths numbering 303,370 or 28·82 per 1,000 of population, against 168,326 or 15·98 in 1899. But there is reason to suspect that many deaths other than fever were recorded under that head, as, it is observed, "whenever a death occurs from causes which the villager does not clearly understand, it is set down to fever." The provincial death-rate from fever was exceeded by eight districts, with ratios ranging from 75·21 in Nimar to 30·43 in Sambalpur.

From dysentery and diarrhœa the registered mortality rose from 13,489 or 1·28 per 1,000 of population in 1899 to 58,474 or 5·55. The lowest death-rate under this head was again recorded by Bhandara district (0·95), Mandla coming next with (0·96); while the highest death-rate from these causes was registered by Sambalpur (16·86), Wardha following (15·62), Betul 14·50, Chandla 10·72, and Chhindwara (10·14).

During the year there were 590 deaths from plague against 584 in 1899. Only seven of the deaths were imported cases, the rest being indigenous. The disease did not succeed in establishing any firm hold in the provinces, as all the deaths among indigenous cases occurred in the Nagpur district. It speaks well for the precautions taken to prevent the disease spreading in these provinces, "lying as they do in the very pathway of and surrounded by infection."

Burma.

In Burma some slight improvement was made in the registration of vital statistics. Births and deaths continued to be recorded in Lower Burma and registration has now been extended to 13 municipal towns in Upper Burma. In the area under registration in Lower Burma 171,183 births were recorded in 1900, giving a birth-rate of 38·37 per 1,000 of population, as compared with 165,229 or 37·04 in 1899. The district rates ranged from 48·17 in Sandoway to 17·43 in Rangoon. The number of deaths registered was 122,714, representing a death-rate of 27·51 per 1,000 of population, against 121,771 or 27·30 in 1899. By districts the death-rates ranged from 19·59 in Prome to 42·39 in Rangoon.

In Upper Burma 11,489 births were registered during the year among a population of 311,605, the birth-rate being 36·87. The registration of deaths extended to a population of 2,454,288, and among them there were 53,496 deaths equal to 21·80 per 1,000. The results obtained, it is remarked, "are sufficiently encouraging, and when a somewhat longer trial has been made, the extension of the system may be found possible."

None of the chief diseases was unusually prevalent during the year. Cholera prevailed in Lower Burma throughout each month of the year and caused 3,440 deaths or 0·77 per 1,000 of population, against 4,942 or 1·11 in 1899. All the districts were visited by the disease, but Toungoo and Sandoway had only one death each, and in five other districts the mortality was small. Thongwa suffered more than any other district, and recorded a cholera mortality of 2·75 per 1,000, followed by Mergui with 2·38 and Myaungmya with 2·28. Six per cent of the 16,757 villages were affected, against 7 per cent in 1899. The months of greatest mortality were February, March, and April. In Upper Burma there were only 41 cholera deaths, and 37 of these occurred in the first quarter of the year.

Small-pox was much less fatal than in 1899, the deaths having fallen from 5,891 or 1·32 per 1,000 to 3,014 or 0·68. Of the 3,014 deaths, 476 or 15·8 per cent. were infants and 1,470 or nearly 49 per cent. were children over one and under 10 years of age. The Irrawaddy division suffered most, its four districts returning 1,270 deaths. In 1899 the Pegu division was the chief sufferer from this disease with 3,013 deaths; but in 1900 the mortality fell to 604. No district was free from small-pox during the year, but only one death was returned by Toungoo. Under this head Upper Burma recorded 2,789 deaths or 1·14 per 1,000 of population under registration.

Deaths ascribed to fever fell from 51,177 or 11·47 per 1,000 in 1899 to 49,888 or 11·18, which was made up of district rates ranging from 20·38 in Sandoway to 5·84 in Amherst. In nine other districts the provincial rate was exceeded. The town death-rate from fever was 8·13, and the rural rate 11·63, as compared with 8·12 and 11·97 respectively in 1899. In only six towns was the mortality above the average for the province, Pegu coming first with 23·88, followed by Myaungmya with 15·71, and Kawkareik with 14·85. The deaths from fever in Upper Burma numbered 19,875 or 8·10 per 1,000 of its population.

The deaths registered under dysentery and diarrhœa during the year aggregated 8,217, or 146 more than in 1899, the death-rates being 1·84 and 1·81 per 1,000, respectively. By districts the highest mortality under this head was recorded by Rangoon 5·16, followed by Thaton 3·72, Kyaukpya 3·71, and Myaungmya 3·15; in the remaining 14 districts the

death-rates ranged from 2·55 to 0·55. In Upper Burma 1,104 deaths were registered from these complaints, being equal to 0·45 per 1,000 of population.

Assam. Registration of vital statistics shows signs of improvement in Assam, but the number of births registered was nearly everywhere far below the estimated probable number. The total number of births registered during the year 1900 was 184,427, giving a ratio of 34·96 per 1,000 calculated on the population of 1901, as compared with 179,027 or 35·45 in 1899. The highest birth-rate was again recorded by Goalpara district, viz., 41·15, followed by Sylhet 39·86, and Cachar 35·20, these being the only three instances in which the provincial rate was exceeded, as the rates of the remaining districts ranged from 31·93 in Darrang to 25·44 in Lakhimpur.

The province was fairly healthy during the year, though the registered deaths rose from 156,595 or 31·01 per 1,000 of population in 1899 to 161,631 or 30·64 per 1,000. There were, however, marked differences between the death-rates of the several districts. The highest was recorded in Nowgong, viz., 53·03, followed by Darrang 44·09, and Goalpara 34·45 ; the remainder being below the provincial average. No districts except Nowgong, Cachar and Kamrup registered so high a death-rate as in the previous year. Taking the province as a whole an excess of births over deaths to the extent of 4·32 per 1,000 was reported, being identically the same as in the previous year.

Cholera was considerably more fatal than in 1899, the number of deaths having risen from 11,288 or 2·24 in 1899 to 23,761 or 4·51 per 1,000 of population. The increase was general, but was most marked in the districts of Nowgong, Darrang, and Kamrup, which recorded the unusually high ratios of 24·95, 9·60, and 7·35 respectively. This violent outbreak occurred during the hot weather, and it is reported that "although Nowgong has often been visited by epidemics of cholera, it never suffered before to such a severe extent." Among tea-garden coolies who travelled up the Brahmaputra Valley in steamers there were 177 deaths from cholera, against only 21 in 1899 ; and among the coolies at the depots, after landing, there where 351 deaths, against 51.

The mortality from small-pox again showed a considerable reduction, the deaths numbering only 975 or 0·18 per 1,000, against 1,565 or 0·31. "Last year," the Sanitary Commissioner writes, "I was able to report the disease as practically non-existent in the Surma Valley. Now I think I may fairly say it plays quite an insignificant part in producing mortality in any portion of the province, which speaks volumes for our vaccination work." Of the total 975 small-pox deaths, Sylhet contributed 531. Over 74 per cent. of the deaths occurred among children under 10 years of age.

There was a marked decrease in the mortality registered under fevers, including kala-azar, the number of deaths having fallen from 91,096 or 18·04 per 1,000 of the population in 1899 to 77,557 or 14·70. Of these 9,036 were from kala-azar against 14,246 in 1899. The provincial fever death-rate was exceeded by three districts, Goalpara ranking first with a rate of 28·02. As in previous years, the bulk of the kala-azar deaths occurred in Nowgong district, but there was again a marked improvement on the previous year's figures, the number of deaths having fallen from 8,192 to 4,661. In Darrang also the mortality under this head fell from 4,101 to 2,979. In his previous report the Sanitary Commissioner expressed the opinion that the epidemic of this disease might be said to be surely if slowly ceasing.

The registered number of deaths from dysentery and diarrhœa rose from 13,835 or 2·74 per 1,000 of population to 14,996 or 2·84. The district rates presented the same extraordinary and unaccountable differences as in former years. Thus in Goalpara the rate was 0·47, and in Kamrup and Nowgong 1·26 and 1·76 respectively, while in Lakhimpur, Darrang, and Sibsagar the rates were 6·11, 4·74, and 4·55 respectively. "I cannot understand," the Sanitary Commissioner remarks, "why the death-rate from acute bowel complaints should always be so much higher in the Sibsagar and Lakhimpur districts than elsewhere in the Assam and Surma Valley districts, and I am inviting the special attendance of the district Civil Surgeons to this anomaly."

Madras. The number of births registered in Madras Presidency during the year was 1,049,199 or 31·8 per 1,000, against 1,048,335 or 31·3 in 1899. The rates for urban and rural areas were 35·7 and 30·9, against 33·0 and 26·9 respectively in the previous year. Towards the close of the year the provisions of Madras Act III of 1899, under which registration of vital statistics is compulsory, were applied to 400 village communities, "and it is scarcely too much to hope," the Sanitary Commissioner with the Government of India remarks, "that surely, if slowly, a complete revolution in the character of the statistics

may be looked for." Considered by districts, the Madras district registered the highest ratio of 46·1, followed by Chingleput with 40·2 ; in thirteen other districts the rate was above 30 per 1,000 ; and in the remaining seven districts the rate was above 25 per 1,000 ; in all but eight of the 22 districts there was an increase in the birth-rate.

The mortality in 1900 was higher than that of the previous year by 95,765, the deaths having risen from 675,094 or 20·1 per 1,000 to 770,859 or 23·4. By districts, Madras City recorded the highest death-rate of 46·8, which is 7·5 per 1,000 higher than that registered in the previous year. In the other districts the mortality ratios ranged from 34·4 per 1,000 in Nilgiris to 16·4 in Ganjam. The Sanitary Commissioner (Dr. King) observed in his report for 1899 : "It is hopeless to attempt, under existing circumstances of registration, to criticise the death-rates reported from districts. They may possibly sink to the almost certainly ridiculous rate of 14·4 per 1,000 in Ganjam, or rise to nearly 30 per 1,000 in South Canara, without its being possible to state definitely what are the errors of omission and commission. The only criterion available is the approach to accuracy of the birth-rate, and the acknowledged existence of special diseases. One cause of deficient death-rate is certainly a tendency to ignore the deaths of infants below one year of age."

Of the chief diseases, the mortality from cholera was more than double that recorded in 1899, the number of deaths having risen from 29,082 or 0·9 per 1,000 to 60,662 or 1·8. All the districts were affected. The disease was most severe in Madura, Tanjore, Tinnevelly, and Godavari, which recorded cholera death-rates ranging between 4·7 and 3·0 per 1,000. In the remaining districts the rates varied from 2·6 in Cuddapah to 0·2 in Ganjam. The average death-rate in municipal and other towns from the disease was 2·8 per 1,000, against 1·5 in 1899, and that in rural tracts 1·8, against 0·8. Twenty of the municipalities were free from cholera, while three recorded death-rates over 10 per 1,000, viz., Perityakulam 20·0, Tinnevelly 13·8, and Palni 12·4.

The mortality from small-pox also increased, the deaths having risen from 16,991 or 0·5 per 1,000 in 1899 to 27,692 or 0·8. Of the districts, Godavari came first with a rate of 3·5, Tanjore 1·7, and South Arcot and Madura 1·2 each. Of the total small-pox deaths, 8,249 or 29·5 per cent. occurred amongst children under 1 year of age, and 7,269 or 26 per cent. among those between 1 and 10 years of age.

From fevers the registered deaths rose from 245,549 or 7·3 per 1,000 of population in 1899 to 288,521 or 8·8. Nine districts had death-rates of over 10 per 1,000, and seven of over 5 per 1,000. Six of the 59 municipal towns returned fever death-rates exceeding 10 per 1,000, the highest being 16·7 in Nandyal, 13·4 in Kurnool, and Kodaikanal 13·2. Among the lowest were Vaniyambadi 0·3, and Tirúpattur 1·5. Dr. King thinks the low rates are probably due to a large proportion of the deaths from fevers in these plague infected localities having been registered under "other causes" to avoid the enquiry as to the cause of death, consequent on a report of fever.

The number of deaths registered under dysentery and diarrhœa in the Presidency was 38,858 or 1·2 per 1,000, against 31,307 or 0·93 in 1899. Of the districts, Madras as usual came first with a death-rate from this cause of 7·7, against 7·9 in the previous year, followed by Chingleput with 3·3, Malabar 2·2, and South Canara 2·1 ; seven other districts had rates over 1 per 1,000. Of the towns, Tuticorin recorded the high death-rate of 10·7 per 1,000, followed by Palamcottah 10·2, Chingleput 9·5, Gudiyattam 9·4, and Guntur 9·4 ; in nine other towns the rate ranged between 8 and 6 per 1,000. The large mortality in these towns is attributed to defective conservancy or a contaminated water-supply, or to both.

Plague was imported into the Presidency towards the close of the year 1898, and eleven districts were more or less affected. Precautionary measures were promptly taken, and the spread of the disease was, as a rule, successfully prevented. By the end of the year 711 attacks with 557 deaths had been reported. In 1899 the attacks rose to 2,385 and the deaths to 1,843. In 1900 the cases fell to 895 and the deaths to 665.

Bombay.

The year 1900 was the most unhealthy in the recent history of the Bombay Presidency, and the vital statistics were affected to an enormous extent by the influence of widespread and very severe famine. Including Sind, 505,652 births were registered during the year, giving a birth-rate of 26·87 per 1,000 of population, the lowest for the past ten years, as compared with 685,348 or 36·42 in 1899. Bombay City, as usual, recorded the lowest rate, viz., 15·42, against 12·88 in the previous year, and Dharwar the highest, 36·24.

The total number of deaths registered in the Presidency rose from 672,269 in 1899 to 1,318,783, and the rate per 1,000 of population from 35·72 to 70·07, which was made up of district ratios ranging from 281·06 in Panch Mahals to 25·42 in Upper Sind Frontier.

The increase of 646,514 deaths was spread over all the districts except three, Belgaum, Dharwar and Kanara. Ahmedabad district recorded the second highest death-rate (173·03), followed by Broach with 163·82 and Kaira with 148·44. Ten other districts had a death-rate above 50 per 1,000. Distress was most severe in the Gujarat districts and the high mortality was greatly swollen by the tide of immigrants from adjacent Native States.

From cholera the deaths during the year rose from 8,579 or 0·46 per 1,000 in 1899 to 163,889 or 8·7, the epidemic being by far the most severe of any during the past 20 years. No district escaped the disease, and in ten of the 24 districts the mortality was over 10 per 1,000. The months of greatest prevalence were May, June and July, when 111,075 deaths occurred. Out of 220 rural circles only 18 enjoyed entire immunity from attack, and out of 56 town circles only five were free from the disease.

Small-pox was more fatal than in any of the previous ten years though the mortality was not great compared with most other provinces. The deaths rose from 1,946 in 1899 to 9,885, the death-rate being 0·52 per 1,000. No district was free from the disease, though some were but slightly visited, and only in four cases did the death-rate exceed 1 per 1,000, the highest rate recorded being 3·71 in Bombay City. Both in the City and in the adjacent districts the influx of starving immigrants from Native States materially contributed to swell the death-rate from small-pox. According to age, 28·86 per cent. of the small-pox deaths occurred among infants under one year of age, and 41·20 per cent. among children between the ages of 1 and 10.

Fever was responsible for more than half-a-million deaths, the number being 543,319 or 28·87 per thousand of population against 228,438 or 12·14 in 1899. These numbers do not include deaths from plague, from which there were 33,196 against 86,596 in 1899. The average fever death-rate was exceeded in seven districts, the mortality being especially high in the famine districts of Gujarat. The collectorate of Panch Mahals headed the list with the high ratio of 167·7 per 1,000, followed by Ahmedabad 111·27, but "the returns from these two districts," the Sanitary Commissioner says, "show serious defects in registration, and fever as a cause of death is much too frequently entered."

The number of deaths ascribed to dysentery and diarrhœa also rose from 74,736 or 3·97 per 1,000 of population in 1899 to 218,243 or 11·59, which is by far the highest ratio on record. In nine of the 24 districts the average death-rate under this head was exceeded, the highest being recorded by Panch Mahals 64·16, followed by Ahmednagar 27·26, Khandesh 26·19, Kaira 23·53, Sholapur 22·13, Broach 17·07, and Nasik 15·17.

From plague 33,196 deaths were reported during the year, giving a ratio of 1·76 per 1,000 of population, against 96,596 or 5·13 in 1899. The outbreak commenced in September of 1896, and at the end of that year 2,086 deaths had been reported, being equal to a ratio of 0·12 per 1,000. Up to the end of 1896 ten of the 24 districts had remained free of the disease, but in spite of precautions to check its progress, plague extended to all but two (Kanara and Panch Mahals) of the districts by the close of 1897, though some were but slightly affected. In 1898 all the districts were affected except three in Sind. Of the 33,196 deaths in 1900, Bombay City contributed 13,285, a decrease of 2,589 on the number reported in 1899, and the plague death-rate fell from 19·69 to 16·48. Poona district followed with a rate of 4·80, Belgaum 4·60, and Karachi 4·36. In six districts no deaths from plague were recorded in the year under notice. An interesting account of the further progress of the plague, and of the measures taken to suppress it, will be found in the Abstract of the Report of the Sanitary Commissioner with the Government of India, at pages 97–102.

Berar.

The year 1900 was exceptionally unhealthy in Berar, and the province suffered throughout the year from severe famine which lowered the vitality of the people and rendered them more susceptible to disease. The number of births registered fell from 144,034 or 50·5 per 1,000 of the population in 1899 to 89,302 or 31·3, which is the lowest birth-rate on record. The low rate was the result of famine and its accompaniments. In all the six districts of the province the birth-rates were much lower than in the previous year, and ranged from 34·2 in Wun to 26·9 in Buldana.

The deaths rose from 113,992 or 39·9 per 1,000 of population in 1899 to 236,022 or 82·7. All districts contributed to the increase, the excess being most marked in Basim, where the rate (110·8) was more than double that of 1899. The influx of moribund people from Hyderabad territory is said to have added greatly to the mortality in Berar. More than half the deaths (130,599) were either children under five (97,899) or old people (32,700) over 60 years of age; "in other words, the weakest suffered most, as might be expected in a famine."

An epidemic of cholera added to the evils of the year, and the recorded statistics show it to have been one of the severest during the last quarter of a century. The disease prevailed throughout the year and claimed 18,375 victims, giving a death-rate of 6·4 per 1,000 of population. In the previous year there were only 541 deaths from cholera. All the districts suffered, Basim most severely; about a third of the cholera deaths occurred in this district, the death-rate being 15·0 per 1,000.

Small-pox was more prevalent, and caused 830 deaths as compared with 305 in 1899, the death-rate being 0·3 per 1,000 against 0·1. More than a half of the deaths (488) occurred in Wun district, bordering on the Hyderabad State, from which a large number of unvaccinated people came, and the fewest number (14) in Ellichpur district. Nearly 58 per cent. of the deaths occurred amongst children under 10 years of age.

The deaths ascribed to fevers rose from 49,938 or 17·5 per 1,000 in 1899 to 84,017 or 29·5. The increase was general in all districts, the death-rate varying between 41·3 in Wun and 20·7 in Ellichpur. The Sanitary Commissioner (Dr. Swaine) writes: "Owing to the drought in 1899 fevers were not very prevalent at the end of that year and the beginning of 1900. As the year 1900 advanced influenza became prevalent, and deaths from it were registered under the head 'Fevers,' and the number of cases of fevers also gradually commenced to increase—mostly of the type of simple continued—due in all probability to the unwholesome water and food the people were consuming, their stamina being reduced, and also to exposure to the very intense heat in the hot weather and wet and damp in the rains."

The number of deaths attributed to dysentery and diarrhœa rose from 20,263 or 7·1 per 1,000 in the previous year to 63,860 or 22·4. Basim district recorded the highest mortality under this head, viz., 33·0, against 6·4 in the previous year, Buldana following with 28·6, which was nearly six times higher than the ratio (5·1) of the preceding year. The other district rates ranged from 24·4 in Akola to 9·2 in Wun. Bad food and bad water were the chief causes for the excessive mortality. Dr. Swaine states: "When the rains commenced bowel complaints increased owing not only to the inclemency of the weather but also to the consumption of green fresh vegetation with which the people supplemented their diet, and gorged themselves, in many cases with fatal results."

Two imported cases of plague were reported in the province during the year. Both were found at Khamgaon, one occurring in January and the other in December.

IV.—JAILS.

Sickness and mortality in 1900.

The health of the jail population of India during 1900 was bad. Famine and disease were prevalent and increased the number of prisoners. "The year was naturally an unfortunate one for the jail population. It was necessary to cope with suddenly enhanced demands on accommodation, and a large portion of the prisoners convicted in some provinces entered jail in a weaker condition than in a normal year."

The daily average sick per 1,000 of average strength rose from 31·4 in 1898 to 32·4, the ratio of admissions into hospital from 792 to 851, and the death-rate from 21·9 to 33·4. In every province except the North-Western Provinces and Oudh, Assam and Coorg, the jail death-rate was higher than in 1899. The most unhealthy administrations were Berar and the Central Provinces. There was a great increase of both morbidity and mortality from cholera among the prisoners. The disease appeared in jails of every province, the chief sufferers being the Central Provinces, Bombay, Berar, and Bengal. The total cases numbered 515, of which 286 were fatal, giving a death-rate of 2·5 per 1,000 of average strength against 3·7 amongst the general population.

The following statement shows the sickness and mortality among all classes of prisoners in the jails and subsidiary jails of the several provinces for 1900, as compared with the previous year :—

Provinces.	1899.			1900.		
	Ratio per 1,000 of Average Strength.			Ratio per 1,000 of Average Strength.		
	Admissions.	Daily Sick.	Deaths.	Admissions.	Daily Sick.	Deaths.
Bengal	1,034	34	23·4	1,173	39	40·3
North-Western Provinces and Oudh.	792	38	22·2	764	36	22·1
Punjab	1,107	33	18·8	1,239	38	23·6
Burma	384	27	18·7	555	28	21·2
Central Provinces	863	27	24·4	934	30	69·0
Assam	982	73	48·0	817	35	22·8
Coorg	815	29	126·7	628	24	54·6
Madras	411	22	16·9	412	23	25·4
Bombay	599	25	25·2	778	25	56·8
Berar	445	13	13·3	943	27	79·9
India	792	31	21·9	851	32	33·4

Bengal.

The health statistics of the Bengal jails for 1900 are unsatisfactory reading. The admissions into hospital were in the ratio of 1,173 per 1,000 of average strength, against 1,034 in 1899, the average daily sick-rate rose from 34 per 1,000 to 39, and the death-rate from 23·4 to 40·3. These results are the more unsatisfactory as the death-rate among the general population was less than the jail death-rate by over 3 per 1,000. Among all classes of prisoners there were 837 deaths, and of these 731 were convicts. The high death-rate in the jails was directly due to the poor condition of many of the prisoners when admitted, for while among prisoners who had been less than six months in jail the death-rate was 54·7 per 1,000, it was only 36 per 1,000 among those between six months and a year in jail. The prevalence of cholera was another cause of the high mortality. From this disease there were 78 deaths against only 3 in the previous year. Besides cholera, the diseases which contributed chiefly to the convict death-rate (39·6 per 1,000) were dysentery 180 deaths, respiratory diseases 130, pneumonia 79, and malarial fever 54. Out of 48 jails the death-rate among convicts exceeded 60 per 1,000 in 11, the highest being Daltonganj 234·5, Faridpur 91·3, Motihari 88·0, Chapra 86·9, Jalpaiguri 83·8, Barisal 73·5, and Hooghly 71·8. In the first three and the last of these there were severe epidemics of cholera, and the others are all situated in the most unhealthy districts in the province. In three jails there were no deaths.

North-Western Provinces and Oudh.

The sanitary history of the jails of the North-Western Provinces for 1900 is again satisfactory. Though the provinces were not free from epidemic disease, the health of the prisoners was fairly good, cholera, small-pox, and debility being the only diseases with increased mortality. The admissions into hospital fell from 792 per 1,000 of average strength in 1899 to 764, the daily average sick-rate from 38 to 36 per 1,000; the death-rate was 22·1, practically the same as in the previous year (22·1). Of the 55 jails in the province there were no deaths in one, and 23 others recorded death-rates below the provincial jail rate. The highest mortality (100·8) occurred, in Lalitpur, a fifth class jail with an average strength of 119, followed by Jhansi 65·4, Fatihpur 55·0, Banda 48·2, Bareilly 45·2, Cawnpore 40·9, and Mirzapur 40·0. The high death-rates in the Lalitpur and Jhansi jails were greatly due to the bad state of health of an exceptionally large number of the prisoners admitted, and to the transfer of most of the healthy prisoners to other jails, whilst the old, weak and sick were kept. Chief among the jails with a low mortality were Muzaffarnagar, with only one death on an average strength of 196, and Bara Banki with four deaths. Only six fatal cases of cholera were reported during the year. Of other diseases, dysentery was accountable for 132 deaths against 144 in 1899. From pneumonia there were 102 deaths against 121, from tubercle of the lungs 84, and from other respiratory diseases there were 18 deaths. Of the total 687 deaths 634 were of convicts, their death-rate being 22·0 per 1,000, against 21·8 in the previous year.

Punjab.

The health of the prison population of the Punjab was not so good as in 1899. The admissions to hospital per 1,000 of average strength rose from 1,107 in 1899 to 1,239, the daily sick-rate from 33 to 38, and the death-rate from 18·8 to 23·6. The death-rate of the free population was 47·69, more than twice as high as that of the jails. The predisposing causes of the high mortality among the jail population were the poor health of many of the prisoners on admission and the severe epidemic of malarial fever during the autumn months. Cholera made its appearance for the first time since 1892, but there were only 12 deaths from the disease, and nine of these occurred in Mung Rasul jail. The average death-rate was exceeded in 13 jails, the highest being 65·04 in Delhi, 56·34 in Karnal, 43·29 in Ferozepore, 40·16 in Jullundur, 39·47 in Dharmsala, 33·71 in Lahore Female jail, 30·61 in Abbottabad, and 30·06 in Ludhiana. In four jails there were no deaths. Of the total 363 deaths, all but 33 were of convicts, giving a death-rate of 23·72. The most fatal disease was dysentery, which contributed 63 deaths or 14 more than in 1899. More than a third of the deaths occurred from diseases of the lungs in one form or another.

Burma.

The health of the prisoners in the Burma jails was satisfactory throughout the year. The admissions to hospital per 1,000 of average strength fell from 584 to 555, the daily sick-rate rose from 27 to 28, and the death-rate from 18·7 to 21·2. In a few jails the accommodation was temporarily overstrained on occasions, but the pressure was relieved by transfers elsewhere. Of the 265 deaths which occurred during the year, all but 18 were of convicts, the death-rate being 20·27 against 18·44 in 1899. There were 33 cases of cholera with 20 deaths, which were spread over six jails; but the largest and only important outbreak occurred in Bassein jail, which returned 22 cases and 14 deaths. In the previous year there were 23 deaths from cholera. Ten of the 31 jails recorded death-rates exceeding the provincial average, but in several cases the average strength was small. The death-rate from all causes was highest at Bhamo (186·67) and Shwebo (72·85), while in eight jails there were no deaths during the year. Moulmein retains its reputation for unhealthiness, the number of admissions to hospital for dysentery alone being 298 out of a total for the whole province of 986.

Central Provinces.

The vital statistics of the jails of the Central Provinces for 1900 are very unsatisfactory, which is not surprising, as famine and disease were prevalent during the year, and increased the number of prisoners and made their physical condition bad. The ratios of admissions into hospital, of daily sick and of deaths, which in 1899 were 863, 27 and 24·4 per 1,000 of average strength, rose to 934, 30 and 69·0 respectively in 1900. All the jails except two were overcrowded at some time, but relief was obtained by utilizing worksheds inside the jails and by extra mural camps. "On the whole" the Inspector General remarks, "the vital statements seem to me to bear out the opinion I formed while inspecting in 1900, viz., that the jails fulfilled very successfully the extra function thrown on them by the famine of serving as hospitals for famine-stricken criminals." The average death-rate was made up of jail-rates varying from 190·14 in Seoni to 24·58 in Damoh. In seven other jails the death-rate was over 100 per 1,000.

Nine jails recorded cholera cases, the total being 51 with 35 deaths. In the previous year all the jails were free from cholera except Bilaspur, where there was one death from it. Under all other chief causes the mortality was greater than in 1899. Of the central jails, Raipur had the highest death-rate (66 per 1,000). This was due to a lingering epidemic of cerebrospinal fever which produced 22 cases and 21 deaths during the year. All kinds of expedients were resorted to, but the only efficacious one to ward off attacks was found to be to considerably reduce the population inside by establishing extra mural camps. All but 40 of the 392 deaths occurred among convicts, the death-rate being 68·2 per 1,000, against 24·4 in 1899.

Assam.

There was a marked improvement in the health of the prison population of Assam, the rate of admissions to hospital having fallen from 982 per 1,000 in 1899 to 817 in 1900, the daily sick-rate from 73 to 35, and the death-rate from 48·0 to 22·8. This great improvement in the death-rate was due to the greater care and attention which are now bestowed on the health of prisoners, to improved dietary, and also to the prohibition of extra mural labour during the unhealthy periods of the year. In only three of the 24 jails was the average strength above 100, viz., Sylhet, Tezpur, and Gauhati, and these three accounted for 31 out of the total 37 deaths. In the other jails the average strength varied from 6 to 88. In sixteen jails there were no deaths. All but two of the 37 deaths occurred among convicts, being in the ratio of 23·92 per 1,000 against 49·73 in 1899. There was only one case of cholera, and this occurred in Nowgong jail, terminating fatally; in the previous year there were 18 deaths from this disease. From dysentery and diarrhœa there were 10 deaths, and from malarial fevers 8.

Madras.

In the jails of Madras Presidency the general health of the prisoners was not so good as in 1899. The hospital admission rate rose from 411 per 1,000 of average strength in 1899 to 412, the daily sick-rate from 22 to 23 per 1,000, and the death-rate from 16·9 to 25·4. These results are mainly attributable to the unhealthiness of the season and its effect upon an exceptionally large jail population, a considerable portion of which was admitted into jail in impoverished health. From all the chief diseases the mortality among Madras prisoners was in excess of that of the previous year. Cholera appeared in an epidemic form in the Nellore and Russellkonda Hill jails, and in a sporadic form in four others. Of the total 19 deaths from this disease Nellore contributed 10. Excluding cholera there were only two deaths in this jail in an average strength of 233. Of the larger or central jails, Cannanore and Trichinopoly were the only ones in which the average jail death-rate of the Presidency was exceeded, the mortality in the former being 48·33 and in the latter 30·94. The highest death-rate was recorded by Russelkonda 72·75, followed by Nellore 51·50. In four other jails the mortality exceeded the rate for the Presidency; while in four jails there were no deaths. Of the total 326 deaths convicts contributed 287, representing a ratio of 27·50 per 1,000 of average strength, as compared with 16·70 in 1899.

Bombay.

The vital statistics of the jails in the Bombay Presidency were also much affected by the abnormal condition of the year. In most prisons there was considerable overcrowding, and although it was relieved as far as possible by transfers and by the provision of temporary accommodation, congestion was unavoidable to some extent. This and the feeble state in which convicts were admitted resulted in greater sickness and mortality. The rate of admissions to hospitals per 1,000 of average strength rose from 599 to 778, the daily sick-rate (25 per 1,000) was the same as in 1899, and the death-rate rose from 25·2 to 56·8 per 1,000. In five jails the death-rate was above the average rate for the Presidency, the highest being 126·5 in the Common Prison, Thana following with 107·0, Sind Gang 65·0, Ahmedabad 60.0, and Dhulia 57·2. Of the total 836 deaths, 571 occurred among the convicts, their death-rate being 48·4 against 25·9 in 1899, and 263 among undertrials, their death-rate being 92·1 per 1,000 of average strength. The chief causes of mortality were dysentery and diarrhœa 134 deaths, respiratory diseases 97, including cholera 72, and tubercle of the lungs, &c., 42. The most serious outbreaks of cholera were at Thana and Dhulia. In the former jail there were 38 deaths from this disease, representing a death-rate of 62·8, and in the latter 24, equal to a death-rate of 25·9 per 1,000 of average strength. From plague there were 32 deaths among the prisoners, of which 23 proved fatal, against only eight deaths in the previous year.

Berar.

Owing to the severe famine which prevailed in Berar in 1900 and to the general unhealthiness of the year the health of the jail population was exceptionally bad. The rate of admissions into hospital per 1,000 of average strength rose from 445 to 943, the

daily sick-rate from 13 to 27, and the death-rate from 13·3 to 79·9. The largest number of deaths in any previous year was 62 in 1897, but during the year under notice 154 deaths were recorded. The heavy mortality was, however, confined to three jails, Amraot and Akola having had 62 deaths each and Basim 24. The extraordinarily high death-rates of these three jails, viz., 136·9 at Basim, 105·7 at Amraoti and 89·28 at Akola were in a great measure due to the bad state of health of the prisoners on admission. Of the 24 deaths in Basim jail 15 were from dysentery and diarrhœa. At Amraoti an epidemic of influenza at the begining of the year, accompanied with a peculiarly fatal form of pneumonia, resulted in 13 deaths, an outbreak of cholera in this jail also resulted in 8 deaths, and from dysentery and diarrhœa there were 22 deaths. At Akola 11 deaths were from pneumonia, 3 from cholera and 19 from dysentery and diarrhœa. All but five of the 154 deaths occurred amongst convicts, their death-rate being 90·49 per 1,000, as compared with 13·52 in 1899.

V.—VACCINATION.

General results.

During 1900-01 there were 7,863,711 persons vaccinated in the several provinces of India, being a decrease of 234,546 on the number of the previous year. The falling off was chiefly in the Central Provinces, Berar, and Bombay, where famine and epidemic disease prevailed, and where exceptionally low birth rates and high mortality were returned. According to age, 3,076,214 children under one year of age, and 3,126,819 children between the ages of one and six years were successfully vaccinated during the year. The proportion of population protected against small-pox by the year's operations ranged from 62·8 in Coorg to 25·9 in Bombay. In the vaccination of infants the best results were obtained in the Punjab, followed by Berar, Bombay, the North-Western Provinces and Oudh, and the Central Provinces, where 55·7, 47·1, 45·7, 44·1, and 42·3 per cent. respectively of the children born during the year (estimated at 40 per 1,000 of population) were protected against small-pox. In the remaining provinces the percentage ranged from 33·5 in Burma to 12·2 in Coorg.

Statement showing the total number of persons successfully vaccinated during the year 1900–01 :—

Province.	Population among whom Vaccination was carried on (Census of 1891).	Number of Persons vaccinated.	Ratio of successful Vaccinations per 1,000 of Population.	Number of Children successfully vaccinated.		Percentage of Children born during the Year (calculated at 40 per 1,000 of Population) successfully vaccinated.
				Under One Year of Age.	Between One and Six Years of Age.	
Bengal	71,050,302	2,346,311	31·6	589,376	1,404,838	20·7

TOTAL	227,079,128	7,863,711	31·8	3,076,214	3,126,819	33·9

Bengal.

The total number of vaccinations performed in Bengal during 1900–1901 was 2,346,311 of which 2,248,015 were successful, against corresponding figures in 1899–1900 of 2,252,521 and 2,221,210. This shows an increase of 93,790 vaccinations in 1900–1901, which was spread over 31 districts, the increase being most striking in Mymensingh (16,492), Chittagong (10,958), and Pabna (10,043). In 18 districts there was a decrease, the most marked instances being Balasore (13,254), Sonthal Parganas (12,295), Bankura (12,232), and Saran (11,267). In some cases the decrease was attributed to plague and in others to the unusual floods of September, or to the prevalence of malarial fever and cholera. The primary operations numbered 2,227,942, of which 97·75 per cent. were successful. According to age, 589,376 of the successful primary vaccinations were of children under one year of age, and 1,404,838 were between one and six years. For the whole province the successful vaccinations were in the proportion of 31·6 per 1,000 of the population. Estimating the births during the year at 40 per 1,000, the percentage of infants successfully vaccinated was 20·7, which is below that attained in any other province except Coorg.

Three methods of vaccination are practised in the province—(1) with lymph taken direct from the calf, from which 280,502 operations were performed; (2) with calf lymph prepared with lanoline, 220,347 operations; (3) with human lymph taken by arm to arm transfer, 1,727,093 operations. Compared with the previous year's figures there was an increase of 38,671 in the number of primary operations performed direct from the calf.

North-Western Provinces and Oudh.

In spite of the fact that most of the experienced vaccinators were deputed on plague duty and that it was necessary to use much caution in conducting operations where plague prevailed, the number of persons vaccinated in the North-Western Provinces and Oudh during 1900–01 rose from 1,511,431 in the previous year to 1,549,409. The increase was spread over 38 districts, the most marked being Bara Banki 9,706. Of the 1,414,776 successful primary cases, 831,483 were infants and 510,483 were children over one and under six years of age. Estimating the birth-rate at 40 per 1,000 of the population, 44·1 per cent. of the births were successfully vaccinated during the year. Calf lymph is only used at present to a small extent, arm-to-arm vaccination being generally practised throughout the provinces.

The provinces are divided into two circles for the purposes of control, each being in charge of a Commissioned Medical Officer, acting as Superintendent of Vaccination and Deputy Sanitary Commissioner. In the first or western circle, the average ratio of successful vaccinations was 32·55 per 1,000 of the population. In the second or eastern circle, the average ratio was 29·87. The Vaccination Act is in force in all the municipalities, but the thoroughness of enforcement still varies considerably. There was a decrease of 3,381 in successful primary vaccinations in these towns, and the proportion of persons successfully vaccinated per 1,000 of population declined from 37·97 per 1,000 in 1899 to 36·60.

Punjab.

There was a falling off in the aggregate number of vaccinations in the Punjab in 1900-01 of 160,578, as compared with the preceding year, viz., from 943,074 to 782,496. This is accounted for by the decrease of over 150,000 births, scarcity, malarial fever, a general unhealthiness which rendered children unfit for vaccination, and other causes. The primary vaccinations numbered 627,754 with a percentage of success of 94·44. The decrease is most notable in the Hissar district (31,526), Umballa (16,882), and Gurdaspur (14,711), the falling off being attributed mainly to the high mortality and sickness amongst children and to a small birth-rate. The number of successful cases among children under one year of age fell from 547,113 or 66·5 per cent. of the births, calculated at 40 per 1,000 of population, to 462,392 or 55·7 per cent. The provincial ratio of persons successfully vaccinated per 1,000 of the total population was 33·3, against 39·9 in the previous year. At the end of the year the Vaccination Act was in force in 25 towns and 12 cantonments.

Burma.

The total number of persons vaccinated in Burma during the year 1900–01 was 410,461, as compared with 490,887 in the previous year, showing a decrease of 80,426 operations. Out of 392,719 primary cases, 91·7 per cent. were successful, against 94·8 in the previous year. The number of infants protected was 109,009, equal to 33·5 per cent. of the births, estimated at 40 per 1,000 of the population. The returns for the Rangoon municipality continue to be unsatisfactory. The number of primary vaccinations fell from 2,457 to 2,265 and re-vaccinations from 2,899 to 2,677 ; while only 1,046 children under one year of age were successfully vaccinated out of a total of 3,143 births. As far as possible work was carried on with prepared animal lymph, but owing to the depots failing to meet demands, arm-to-arm vaccination had to be resorted to. As regards the attitude of the people, inoculation is carried on throughout the province, and Civil Surgeons generally, the Sanitary Commissioner states, report passive opposition to vaccination in favour of inoculation. The Act for the compulsory vaccination of children is in force in all the municipalities of the province, and, with a view to further provide for compulsory vaccination in the province, the Burma Vaccination Law Amendment Act was passed in 1899. This Act empowers Superintendents of Vaccination in Rangoon Municipality, and in other municipalities to which the Act may be extended, to require unprotected persons to be vaccinated, and provides also for the compulsory vaccination of inmates of lodging houses or coolie barracks. These powers, the Sanitary Commissioner with the Government of India observed, in his report for 1899, "should avail for the protection of the coolie immigrants in Rangoon, a class very liable to harbour and spread small-pox, the compulsory vaccination of whom was discontinued in August, 1896."

Central Provinces.

In the Central Provinces 455,397 persons were vaccinated during the year, showing a decrease of 53,926 on the number of the previous year. The falling off was entirely under primary vaccinations and was due to the low birth rate and high infant mortality which considerably reduced the number of children available. The closing of the relief camps, it is stated, also lessened the facilities, which had existed in the previous year, of vaccinating large numbers of children at a time. Primary vaccinations fell from 456,857 to 385,493 and the percentage of success from 96·97 to 96·50. The ratio

of successful vaccinations in the year to the total population was 33·42 per 1,000, as compared with 37·92 in 1899–1900. In the protection of infants there was a falling off of 87,845, the number vaccinated under one year of age during the year having fallen from 306,669 to 218,824, the latter number being equal to 42·3 per cent. of the births estimated at 40 per 1,000 of population. Animal lymph was used in the bulk of the vaccinations, and worked very successfully. Arm-to-arm vaccination is practised in very few places. With the lymph obtained from calves, 233,969 children were vaccinated during the year, and of these 223,737 were successful. The use of glycerinated lymph was attended with satisfactory results, the percentage of success attained being 86·97 against 86·27 in the previous year.

Assam.

During the year 1900–01 271,466 vaccinations were performed by all agencies in the province of Assam, showing a small decrease of 799 on the previous year's work. Of the total operations 251,263 were primary cases, and of these 95·99 per cent. were reported as successful, against 98·50 in the previous year. The Compulsory Vaccination Act continued in force during the year in the same 11 towns as in the previous year, wherein nearly 70 per cent. of the available children under one year of age were vaccinated. The number of infants successfully vaccinated in the province was 53,146, representing only 21·7 per cent. of the births, estimated at 40 per 1,000 of the population, and the proportion of the population successfully vaccinated in the year was 42·0 per 1,000. The Vaccination depôt at Shillong continued to work successfully, and 387,557 tubes were loaded with calf lymph against 317,382 in the previous year. The work of the province was entirely performed with this lymph.

Madras.

The total number of vaccinations performed in the Madras Presidency during 1900–1901 was 1,257,883, being an increase of 98,474 on the operations of the previous year. The increase was mainly attributable to the steady subsidence of the plague inoculation scare which operated detrimentally to vaccination in the two previous years. Of the total, 1,181,375 were primary cases, of which 91·9 per cent. were successful, practically the same as in the previous year, viz., 91·8. The number of children under one year of age successfully vaccinated rose from 324,249 to 350,763, which represented only 24·6 per cent. of the estimated births. Vaccination is compulsory in all municipalities, and the number of operations performed by municipal vaccinators rose from 120,442 to 131,195. In the town of Madras the number of operations performed was 32,571, an increase of 7,612 on the previous year. Of the 21 districts, six recorded a decrease of work. Chief among the causes assigned for the decline is the absence of members of the vaccination staff, without substitutes, on census and other special duty. Nearly all the operations were performed with animal lymph, and the best results were obtained, as usual, from calf-to-arm vaccination, with a percentage of success of 98·8.

Bombay.

There was a considerable decrease in the number vaccinated in the Bombay Presidency in 1900–1901 as compared with the previous year. The out-turn of vaccination work throughout the Presidency fell from 768,672 operations in 1899–1900 to 661,001. The decrease is attributed to the widespread famine and to epidemic disease which lowered the birth rate and raised the infantile mortality rate. The total primary cases fell from 679,467 to 586,478, the percentages of success being respectively 92·84 and 90·86. No other lymph except animal and human was used in the Presidency during the year. The relative results obtained are not given in the Sanitary Commissioner's report, but these are to be supplied in future. In the City of Bombay vaccination with animal lymph has been in use for many years past. Of the successful primary cases, 76 per cent. were infants under one year of age. Reckoning the births in the Presidency at 40 per 1,000 of population, 45·7 per cent. were protected from small-pox. No inoculation was reported to have been practised anywhere during the year, except in the towns of Karachi and Hyderabad. The protection afforded to the population by the year's operations was in the ratio of 25·9 per 1,000.

Berar.

Famine and epidemic disease and the absence of the staff on special duty connected therewith greatly interfered with vaccination work in Berar during the year. The number of persons vaccinated fell from 175,901 in the previous year to 107,788, or a decrease of 68,113. The primary vaccinations fell from 120,772 to 74,707 ; but the percentage of success rose from 95·8 to 96·6. Of the total number of successful primary operations, 54,551 were performed on infants under one year of age ; estimating the births at 40 per 1,000 of population, 47·1 per cent. were protected against small-pox, and the proportion of population protected by vaccination fell from 43·2 per 1,000 in the previous year to 27·3. The decrease in primary vaccinations was spread over all the districts. Owing to the famine, calves in sufficient numbers were not available to raise fresh calf lymph, and

lanolinated calf-lymph manufactured at Amraoti was used from April to November, thereafter to the end of the working season fresh calf-lymph was used. The Sanitary Commissioner continues his statement, showing the efficacy of vaccination in checking small-pox mortality in Berar; the ratio of successful vaccinations per 1,000 of population has risen from 8·92, the mean of five years 1868–69 to 1872–73, to 33·6, the mean of five years ending 1897–98; the mortality from small-pox for the same periods has declined from 2·02 to 0·19 per 1,000. In 1898–99, 1899–1900, and 1900–01, the ratios of successful vaccinations per 1,000 of population were 34·6, 43·2 and 27·3, and the death-rate from small-pox 0·2, 0·1 and 0·3 per 1,000. The Vaccination Act is in force in all the municipal towns.

VI.—MEDICAL INSTITUTIONS.

Civil Hospitals and Dispensaries.

The following comparative statement shows the number of hospitals and dispensaries open in the several provinces of India during 1900 and the previous year, and the number of patients under treatment :—

Provinces, &c.		Number of Institutions.	Number of In-door Patients.	Number of Out-door Patients.	Total Number of Patients.
Bengal	1900	531	50,097	3,417,284	3,467,381
	1899	513	47,897	3,243,346	3,291,243
Calcutta and Howrah	1900	17	28,372	251,822	280,194
	1899	15	24,146	219,302	243,448
North-Western Provinces and Oudh	1900	484	55,394	3,577,776	3,633,170
	1899	374	59,643	3,939,022	3,998,665
Punjab	1900	273	59,328	3,379,034	3,438,362
	1899	272	51,967	3,102,310	3,154,277
Burma	1900	113	36,095	822,594	858,689
	1899	110	34,749	783,290	818,039
Central Provinces	1900	175	13,725	1,330,261	1,343,986
	1899	127	11,434	1,520,208	1,531,642
Assam	1900	128	6,369	696,221	702,590
	1899	115	6,217	617,586	623,803
Coorg	1900	7	1,434	44,276	45,710
	1899	7	1,040	32,713	33,753
Madras	1900	551	64,269	4,621,484	4,685,753
	1899	537	63,184	4,375,053	4,438,237
Bombay	1900	547	50,888	1,485,534	1,536,422
	1899	354	50,902	2,078,979	2,129,881
Berar	1900	48	7,315	318,375	325,690
	1899	48	4,590	327,108	331,698
TOTAL	1900	2,874	373,286	19,944,661	20,317,947
	1899	2,472	355,769	20,238,917	20,594,686

Bengal. The total number of dispensaries at work during 1900 in Bengal, exclusive of the medical institutions at Calcutta, was 531, an increase of 18 on the number of the preceding year. At these there were 3,467,381 patients under treatment, 50,097 being in-door and 3,417,284 out-door patients, against 47,897 and 3,243,346 respectively in the previous year. This shows a total increase of 176,138. "It is to be feared," the Lieutenant-Governor remarks, "that the increase in the number of patients is due as much to the unhealthiness of the year as to the popularity of the Government dispensaries, and it would in all probability have been much greater but for the prevalence of plague in some of the districts which deterred people from seeking medical relief in some of the dispensaries."

There was again a satisfactory increase in the number both of women and children patients. The increase among women amounted to 21,705, the number having risen from 517,858 to 539,563. The proportion of women, however, was much about the same as in the previous year, viz., 17·55 against 17·84 per cent. Of the diseases under treatment at the dispensaries, malarial fevers, skin diseases, and dysentery and diarrhœa were responsible, as usual, for the largest number of cases. From malarial fever there were 629,746 cases, equal to nearly 19 per cent. of the total number of patients, against 623,173 in 1899 ; from skin diseases the number of cases rose from 501,830 to 591,500 ; from dysentery and diarrhœa there were 185,507 cases, against 160,060 in 1899. From cholera the number of patients rose from 10,638 to 21,371. Cases of venereal diseases rose from 81,602 to

82,131. The number of deaths among in-door patients rose from 5,559 or 116·0 per 1,000 of total treated in 1899 to 6,430 or 128·3 in 1900. During the year 656 plague cases were treated in the dispensaries against 2 during 1899, the majority receiving treatment at dispensaries in the Gaya district. A disease locally known as "Batphut," which was ascertained to be prevalent in a portion of Khondmals of the Orissa Tributary States was, under the orders of the Government, investigated and pronounced to be one of virulent syphilis, probably introduced, it is stated, from the Sonpur Native State in the Central Provinces; necessary measures were taken for the treatment of the disease locally. Great attention is paid in these institutions to surgery, and during the year 146,580 operations were performed, against 145,379 in 1899, and of these 191 terminated fatally. Among the more important operations there were 2,388 cases of extraction of the lens.

The following statement shows the number of in-door and out-door patients treated in the several hospitals and dispensaries in Calcutta and Howrah during 1900 and the previous year :—

Name of Institution.	1899.				1900.			
	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.

Grand Total	24,146	219,302	243,448	143·2	28,372	251,822	280,194	172·5

The figures for 1900 show an increase of 32,520 in out-door patients, and of 4,226 in in-door patients. The increases were mainly due to the unhealthiness of the year and to the inclusion for the first time in the Calcutta list of the statistics of the Municipal and Dockyard Dispensaries at Kidderpore, which had hitherto been shown in the provincial list. The death-rate for all the hospitals was 172·5 per 1,000 of the total in-patients, against 143·2 in the previous year. Cholera patients rose from 355 to 728, and the fatal cases from 227 to 445. The increase was most marked in the Campbell Hospital, where 271 cases were treated against 136 in the previous year. Small-pox was more prevalent in Calcutta than in the previous year, and the cases admitted to hospital rose from 42 to 240. Dysentery patients rose from 6,404 to 9,171. The number of patients treated for diarrhœa also rose from 6,673 to 8,949; malarial fever was responsible for 54,571 patients against 46,138. Plague cases treated rose from 229 to 449, and the deaths from 198 to 357. Venereal diseases show an increase of 1,169 patients, the number treated having risen from 11,159 in the previous year to 12,328. Surgical operations increased from 25,109 to 26,023, and death ensued in 188 cases, against 154 in 1899.

North-Western Provinces and Oudh.

During 1900 there were 484 hospitals and dispensaries at work in the North-Western Provinces and Oudh, or 110 more than in the previous year. The number of patients who received medical aid was 3,633,170 against 3,998,665 in 1899. There was thus a decrease

in 1900 of 365,495. The number of in-patients fell from 59,643 to 55,394. The decrease in attendance was due in a great measure to plague preventive measures, which deterred patients from seeking medical relief at Government charitable dispensaries. Of the total number, 51·9 per cent. were men, 22·4 per cent. were women, and 25·7 per cent. were children, the first and last showing a small increase on the figures of the previous year. Among the in-door patients there were 3,099 deaths, against 2,865, and the death-rate rose from 48·0 to 55·9 per 1,000. Of the diseases for which the patients were treated 536,029 were suffering from malarial fevers, a decrease of 125,124 on the number of 1899 ; 4,679 cases of cholera were treated in the dispensaries, against 520, and cases of diseases of the eye fell from 365,369 to 337,464. From venereal diseases there were 81,765 patients, against 82,884 in the previous year. The number of surgical cases rose from 180,190 to 182,986, of which 154,102 resulted in cure and 389 were fatal. Of the total operations 5,373 were for cataract, of which nearly 83 per cent. were successful, as compared with 5,778 operations and a percentage of success of 84 in 1899.

Punjab.

The number of dispensaries at work in the Punjab during 1900 was 273 or one more than in the previous year, but no less than 40 dispensaries had to be temporarily closed in order to provide Hospital assistants for plague and famine duties. During the year 3,438,362 patients were under treatment, being an increase of 284,085 on the number of 1899. The attendance of in-door patients was greater than in the previous year by 7,361, the number having risen from 51,967 to 59,328. Considering the general unhealthiness of the province during the year this large increase is not to be wondered at. Of the diseases for which patients sought relief there were 4,663 cases of cholera, a large increase on 219 in 1899. Owing to the heavy continued rain cases of malarial fever rose from 381,465 to 655,914. Diseases of the eye showed a decrease of 5,683 cases, the number treated in 1900 being 442,699, against 448,382. From venereal diseases there were 33,442 cases under treatment, an increase of 3,440 on the previous year's figures. Among the in-patients there were 4,079 deaths during the year, being in the ratio of 68·7 per 1,000 of the number treated, against a death-rate of 44·1 in 1899. The number of surgical operations amounted to 165,222, which, compared with the previous year, shows a decrease of 4,829 operations ; but the decrease was in minor operations. Of the total operations, 159,851 resulted in cure and 258 were fatal. There were 5,614 cataract operations, and of these 89·9 per cent. resulted in cure.

Burma.

The number of dispensaries existing in Burma at the end of 1900 was 113, or three more than in the previous year. At these, 858,689 patients attended, as compared with 818,039 in 1899. The number of in-door patients rose from 34,749 to 36,095, of whom 26,540 were cured, and 2,724 or 75 per 1,000 died, against 2,611 deaths or 75 per 1,000 in the previous year. Nearly 57 per cent. of the patients treated were Burmese. Malarial fevers, as usual, headed the list of maladies under treatment, the number of cases being 136,619, against 126,373 in the previous year. Cholera was not so prevalent as in 1899, and the number of cases fell from 581 to 221. Cases of venereal disease rose from 24,627 in 1899 to 29,692 Surgical work showed an increase of 1,907 operations, the number performed during the year having risen from 17,154 to 19,061. The number of patients cured, after being subject to operation, was 18,259 and 101 died.

The figures for the Dufferin Hospital are given in the Inspector General's report for 1900 for the first time. The total number of patients during 1900 was 1,223, of whom 512 were in-door. This hospital provides accommodation for maternity and for gynecological cases, besides quarters for 24 pupil midwives, who undergo a course of instruction in midwifery and sick-nursing. Since the opening of the hospital in 1888, 154 nurses have passed out, and of these 14 are at present in the employment of municipalities.

Central Provinces.

The number of hospitals and dispensaries at work in the Central Provinces during 1900 was 175, or 48 more than in the previous year. The total number of patients fell from 1,531,642 to 1,343,986. The decrease, however, extended only to out-door patients, the in-door patients having risen from 11,434 to 13,725. The increase in in-patients was chiefly due to the free admission of cholera and famine-stricken patients and to the exceptional unhealthiness of the year. Among the in-patients there were 2,083 deaths, or 151·2 per 1,000 of total treated, against 892 or 78·0 in 1899. As regards the different kinds of diseases, malarial fevers headed the list with 314,884 cases. From cholera there were 6,566 cases, from dysentery and diarrhœa 79,103 cases, and from venereal diseases 28,489 cases. The number of surgical operations fell from 34,884 in 1899 to 32,472. Of these, 31,631 resulted in cure and 69 in death. Of the more important operations, 731 were for extraction of the lens.

Assam. In the province of Assam there were 128 dispensaries at work during the year, or 13 more than in the previous year. There was a further large increase in the number of patients, the total under treatment having risen from 623,803 in 1899 to 702,590 in 1900. These institutions, it is stated, are steadily becoming more useful and better appreciated by the people. The number of in-patients rose for the first time for four years, viz., from 6,217 to 6,369, and of these 4,040 were discharged cured, 483 relieved, 659 discharged otherwise, and 894 died, the latter representing 140·4 per 1,000 of the total in-patients, against a ratio of 151.5 in 1899. The attendance of men and children increased, while the attendance of women fell off, in spite of the fact that separate consulting rooms were set apart for women at almost all dispensaries. Of the total number of persons who received medical aid, malarial fever accounted for 125,231 cases, including 2,013 suffering from kala-azar, against 3,736 of these cases in the previous year; dysentery and diarrhœa 23,745, and venereal diseases 7,721. Cholera patients rose from 1,449 in 1899 to 2,717. Of surgical cases there were 16,035, of which 15,423 were cured and 41 were fatal.

Madras. Exclusive of the hospitals in the Presidency town there were 537 civil hospitals and dispensaries working in Madras at the close of 1900, or 14 more than in 1899, and at these there were 4,448,881 patients under treatment, exceeding the number of the previous year by 222,573. Of the 44,716 in-door patients, 27,500 were returned as having been cured under treatment, 9,017 as relieved, and 3,356 as otherwise discharged. The deaths numbered 3,442, representing a ratio of 77·0 per 1,000 of the total in-patients, against 54·2 in the previous year. Ulcers and diseases of the skin, malarial fevers, diseases of the digestive system, rheumatic affections, and diseases of the eye were the most common complaints under treatment during the year. Cholera was much more prevalent in the Presidency than in the previous year, and the cases under treatment in the various hospitals and dispensaries rose from 3,234 to 9,571. From venereal diseases there were 79,570 cases, against 78,002 in 1899. The surgical operations rose from 121,261 in 1899 to 137,407. Of these, 131,709 were cured and 146 were fatal.

The number of medical institutions in Madras town remained the same (14) as in 1899, but the number of sick treated rose from 211,929 to 236,872. The in-patients rose from 16,674 to 19,553, and amongst them 9,739 cases were recorded to have been cured or perfectly recovered, 3,819 were relieved, 3,474 discharged otherwise, and 1,501 or 76·8 per 1,000 died, against a rate of mortality in 1899 of 65·6. The increase in mortality was due to cholera in an epidemic form. Of the several diseases for which the patients were treated, malarial fever, diseases of the digestive system, skin, and respiratory system were, as usual, the most common. From cholera there were 344 cases, against 28 in the previous year, from dysentery and diarrhœa 8,081, and from venereal diseases 4,324. Slightly fewer surgical operations were performed, the number having declined from 16,243 in 1899 to 16,226. The results showed that 13,349 cases were cured, 2,234 were relieved, and 127 were fatal.

At the Madras Voluntary Venereal Hospital, which is included in the above hospitals in the city, there were 525 female patients treated during 1899, an increase of 13 on the number of the previous year. Of these, 204 were cured and 14 died.

Bombay. Excluding the 11 medical institutions in the City of Bombay, there were 536 hospitals and dispensaries working in the Presidency at the end of 1900. At these, 1,416,517 patients were under treatment, of whom 32,501 were in-door and 1,384,016 out-door patients, against 32,831 and 2,029,422 respectively in 1899. Malarial fevers, as usual, constituted by far the largest number of cases (523,584), and showed an increase of 175,837 on the figures of the previous year. Next to fever, eye and skin diseases and worms were the most common ailments. All the important diseases except two showed an increase. Cholera cases rose from 630 to 20,002; dysentery cases were also more numerous; and patients suffering from venereal affections rose from 32,861 in 1899 to 46,086 in 1900. Of the in-door patients 22,759 were cured, 2,280 relieved, 1,939 discharged otherwise, and 4,357 died, the ratio of deaths to total treated being 134 per 1,000, against 134 in the preceding year. The total number of patients operated on was 52,123, as compared with 72,518 in 1899, and of these 41,019 were cured and 187 died. The large decrease in the number of operations was mainly under those for abscesses (8,012) and those on the teeth (9,545.)

The total number of patients treated at the 11 civil medical institutions working in the town of Bombay during 1900 showed an increase of 19,446, the figures being 119,905, against 100,459 in the previous year. The in-patients increased in number from 18,071 to 18,387, and of these 10,610 were cured, 2,489 relieved, 1,037 otherwise discharged, and

3,265 died, the deaths being in the ratio of 178 per 1,000 of the in-patients, against 129 per 1,000 in 1899. As usual, local injuries, malarial fevers, and eye diseases were the chief complaints treated. Venereal diseases contributed 4,405 cases, against 3,626. From cholera 75 cases were under treatment; and dysentery cases rose from 1,449 to 2,558, and diarrhœa cases from 3,805 to 4,047. The total number of patients operated on was 10,842, and of these 7,029 were cured, 187 relieved, 68 discharged otherwise, and 206 died.

Berar. There were 48 medical institutions at work in Berar during 1900, the same as in the three previous years. Of these, eight are hospitals wholly maintained by the State. The total number of patients under treatment was 325,690, against 331,698 in 1899. In-patients numbered 7,315, and of these 5,356 were cured and 1,122 died, which gives a death-rate of 153·7 per 1,000. The apparent diminished attendance was more than counterbalanced by the number of patients who were treated at the special hospitals attached to poor-houses and relief camps throughout the province. Malarial fevers continued to head the list of diseases from which relief was sought; nearly a fifth of the total patients were treated under this head; diseases of the eye and diseases of the digestive system came next in order. The number of surgical operations was 9,882, against 11,104 in 1899. Of these, 9,678 were cured and 41 were fatal.

The work of the Lady Dufferin Hospital for women and children at Amraoti continued to show progress. The number of in-door patients rose from 151 in 1899 to 230, but the out-door patients fell slightly, from 6,847 to 6,839. The number of operations performed rose from 120 to 139.

Lunatic Asylums.

Bengal. At the five asylums in Bengal (viz., Dullunda, Dacca, Patna, Cuttack, and Berhampore) 1,123 lunatics, including 234 fresh admissions and re-admissions, were under treatment in 1900, being a decrease of 8 on the number of the previous year. In the course of the year under notice 81 patients were discharged as cured, and 19 as improved or otherwise, and 96 died. Compared with the figures of 1899, the number discharged was less by 34, and the mortality more by 14. At the end of the year there were 906 persons still under detention, or 17 more than at the close of 1899. The improvement in the health of the inmates noticed during the two previous years was not maintained in 1900. The number of admissions to hospital rose from 576 to 962; the average daily number of sick fell from 86 to 97; while the death-rate rose from 96·3 to 106·8 per 1,000 of average strength. The cause of insanity was traceable only in 80 of the 234 fresh admissions, and 23 of these were ascribed to ganja smoking. The results of the working of dairy farms at the asylums were not on the whole so satisfactory as in the previous year. At Dullunda there was a profit of £58 as compared with £55 in the previous year. At Dacca the dairy was worked at a loss owing to bad management. The dairy farm at Berhampore also showed a smaller profit. The usefulness of the dairy farms, however, is not indicated so much in the profits as in the supply of pure milk and in the congenial work which they afford to the lunatics.

In the Bhowanipur Asylum, containing European and Eurasian patients only, the inmates during 1900 numbered 53, or one less than in the previous year. Of this number 37 were under detention at the beginning of the year, and 16 were subsequently admitted. In the course of the year 10 patients were discharged, 4 died, and two were despatched to Europe as still insane, leaving 37 under confinement at the close of the year. As regards the health of the patients during the year, there were only 6 admissions to hospital, the same as in the previous year, and 4 deaths, also the same as in 1899.

North-Western Provinces and Oudh. The inmates of the four lunatic asylums (Agra, Bareilly, Benares, and Lucknow) in the North-Western Provinces and Oudh in 1900 numbered 1,358, including 243 fresh admissions during the year, against 1,349 in 1899. Before the close of the year 161 patients were discharged, of whom 138 were reported as cured, 28 were made over to friends, 82 died, and 3 were discharged, leaving 1,112 under treatment at the end of the year. There was less sickness in the asylums than in the previous year, the total number of sick treated in hospital having fallen from 1,313 to 1,140, but the total mortality rose from 72 to 82. The health of the Bareilly asylum was very unsatisfactory during the year, and the number of deaths (32) was the largest recorded for many years, phthisis and cholera being the chief causes of mortality with 10 and 6 deaths respectively. Cholera was not present in any other asylum. The scheme for a large central institution at Agra, under the charge of a whole-time Superintendent, was being carried out. Buildings for Europeans and Eurasian lunatics were completed, and the plans of the other new buildings were approved.

Punjab. The new Central Lunatic Asylum for the province of the Punjab was opened on the 1st March, 1900, and within that month the patients from the old asylums at Lahore and Delhi were transferred to it, and the two institutions were permanently closed. The total number of lunatics in the Punjab lunatic asylum during 1900 was 608, including 151 fresh admissions, against 607 in 1899. At the end of the year the number was reduced to 482 by the discharge of 76 patients, 38 as cured, 34 made over to friends, and 4 otherwise discharged, and 50 deaths. As regards the health of the inmates of the asylum, the number of admissions to hospital during the year was 436, the daily average sick 42, and the death-rate 105·9 per 1,000 of average strength. Of the 50 deaths, 11 were from tuberculosis of the lungs, 11 from pneumonia, and nine from dysentery. Of the total number of admissions, in more than one half (81) the cause of insanity was unknown.

Burma. The Rangoon Asylum is the only one in the province of Burma, and has accommodation for 404 insanes. During 1900 there were 473 patients in the asylum, including 105 fresh admissions, and the total was reduced at the close of the year to 390 by the discharge of 60 patients for different causes, and the death of 23. As regards the general health of the inmates, the daily sick rose from 13·8 to 17·1, but the deaths fell from 30 or 83·3 per 1,000 of average strength to 23 or 60·3.

Central Provinces. In the two asylums of the Central Provinces (Nagpur and Jubbulpore), there were 393 lunatics under treatment during 1900, a decrease of 2 on the number in 1899. In the course of the year 58 patients were discharged as cured or otherwise, and 23 died, leaving 312 still under treatment at the end of the year. The health of the inmates was not quite so good as in the previous year. The admissions to hospital at Nagpur rose from 69 to 98, and at Jubbulpore they fell from 93 to 90. The increase at Nagpur was due to the fact that many debilitated patients were kept in hospital for long periods during the year. Of the total 23 deaths, Nagpur recorded 19, being in the ratio of 115·2 per 1,000 of average strength, against 11 or 63·6 in 1899. At Jubbulpore there were 4 deaths, being in the ratio of 24·8 per 1,000, against 3 or 19·4 in 1899. Of the 50 admissions during the year, 17 were returned as due to unknown causes.

Assam. There is only one lunatic asylum in the province of Assam, and this is situated in Tezpur. The total number of lunatics under treatment in the asylum during 1900 was 150, or three more than in the previous year. Of these, 31 were fresh admissions. At the close of the year the patients in the asylum were reduced to 114, 19 of the total number having been discharged, and 17 having died. The health of the inmates was not satisfactory. There were 159 admissions to hospital, as compared with 57 in 1899. The daily average sick was 11, and the number of deaths was more by eight than in 1899, while the death-rate rose from 71·1 per 1,000 of average strength to 138·6. It is explained that five of the deaths were due to phthisis, which could not be prevented. The causes of insanity were unknown in 10 of the fresh admissions.

The increased sickness and mortality were due chiefly to diarrhœa and dysentery, but there was also a general increase all round.

Madras. At the commencement of 1900 there were 554 patients under treatment in the three lunatic asylums (Madras, Vizagapatam, and Calicut) of the Madras Presidency. During the year 161 fresh cases were admitted, bringing the total population up to 715, or 13 less than the number in the preceding year. In the course of 1900 there were 107 cases of discharge, and of these 96 were cured or improved. The accommodation was ample, and there was no overcrowding in any of the asylums during the year. On the whole there was less sickness among the patients than in the previous year, and there were no epidemics in the Madras and Calicut Asylums; but in the month of May influenza was prevalent in the asylum at Vizagapatam, and 26 cases were admitted. The daily average sick fell from 81 to 74, and the deaths from 59, or 101·1 per 1,000 of average daily strength, to 49 or 89·8. Of the total 49 deaths the Madras Asylum contributed 41, giving a death-rate of 104·2 per 1,000 on an average strength of 394, against a ratio of 117·7 in 1899. The death-rates of the other two asylums, Vizagapatam and Calicut, were 57·0 and 49·0 per 1,000 respectively, against 28·0 and 77·2 in the previous year. Of the 41 deaths in the Madras Asylum five died within less than three months of admission, while 14 deaths occurred among patients of over five years residence in the Asylum. Of the 161 fresh admissions, the causes of insanity were unknown in 78 or 48·45 per cent.

Bombay. The total population of the six lunatic asylums of the Bombay Presidency (Colaba, Ratnagiri, Poona, Dharwar, Ahmedabad, and Sir Cowasji Jehangir, Hyderabad) was 1,089, including 285 fresh admissions, against 1,114 in 1899. In the course of the year 191

patients were discharged, 73 of them as cured, and 139 died, leaving 759 under treatment at the close of the year. There was considerably more sickness in the asylums than in 1899, the daily average sick having increased from 37 to 42, and the death-rate from 108·2 per 1,000 of average strength to 178·0. Of the 139 deaths, diarrhœa and cholera accounted for 38. Slightly more than half the deaths (71) occurred in the Colaba Asylum, the death-rate being nearly 240 per 1,000 of average strength, against 168·2 in the previous year. The highest death-rate was recorded at the Sir Cowasji Jehangir Asylum at Hyderabad, viz., 271 per 1,000, the result of 28 deaths.

Medical Schools.

Bengal.

The number of medical schools open in Bengal during 1900–1901 was 10, or one more than in the previous year. The Medical College, Calcutta, and four of the medical schools are maintained by Government, the rest are unaided. The college is affiliated to the University, and prepares candidates for its various medical degrees. The four Government medical schools train pupils as Civil Hospital Assistants, and the five unaided schools follow their own standards for private practice.

The students of the Medical College are required to undergo three University examinations during their five years' study, viz., the Preliminary Scientific examination at the end of the second year, the first L.M.S. or the first M.B. examination at the end of the third year, and the second L.M.S. or second M.B. examination at the end of the fifth year. The total strength of the College at the end of the session 1900–01 was 569 (including 12 women), against 502 in the preceding year. As regards the examinations, 214 candidates were successful out of a total of 506, the successes being at the rate of 42·29 per cent., as compared with 37·35 per cent. in 1899–1900. Of the 214 successful candidates, 49 passed the Preliminary Scientific L.M.S. examination, 42 passed the first, and 65 the second L.M.S. examinations; 26 passed the Preliminary Scientific M.B. examination; six passed the first and three the second M.B. examinations. For the combined Preliminary Scientific and First L.M.S. examinations, five passed the first L.M.S examination and 13 the Preliminary Scientific L.M.S. examination; and for the combined Preliminary Scientific and First M.B. examinations one passed the first M.B. examination and four the Preliminary Scientific M.B. examination.

Sixteen pupil nurses passed their examinations and received midwife's certificates. Ten native *dais* passed in midwifery from the Eden Hospital, and also received certificates.

The total number of students attending the four Government Vernacular Medical Schools at Calcutta, Patna, Dacca and Cuttack was 607 (including 35 women), against 637 (including 37 women) in the previous year. The largest attendance was at the Campbell School, Calcutta, the number of students being 197 (including 19 women). The total number of passes was 88 (including only two women from the Dacca school).

North-Western Provinces and Oudh.

The number of pupils attending the Agra Medical School in 1900–01 was 232 (including 50 women), or 12 less than in the preceding year. "The general conduct of the pupils, both male and female, during the year," it is reported, "was satisfactory. With regard to their ability and application it is more difficult to speak. The pass lists show the usual variations in the number of marks gained in the different classes, most of which are up to the average of the past five years." Of the 182 male students, 34 passed out into the service. As regards the examination of women students, five in the first class obtained their diplomas.

Punjab.

The average attendance at the Lahore Medical College and School was more by 14 as compared with that of 1899–1900, viz., 443 against 429. Of these 181 were in the College, and 262 in the Medical School. The results of the year's examinations show that for the Preliminary Scientific Examination, 9 out of 23 candidates passed. In the first L.M.S. and M.B. examinations, 28 candidates out of 45 passed, against 18 out of 50 in the previous year, and in the second L.M.S. and M.B. examinations 21 out of 43 passed, against 28 out of 50; in all 58 out of 111, or 52 per cent. were successful, as compared with 65 out of 126, or 51 per cent. in the previous year. In the final examination for the hospital assistant diploma 52 passed out of 65, or 80 per cent. Of the students on the rolls 14 were women.

The Medical School for Christian women continues to make progress and to do good work at Ludhiana. The object of the institution is "to provide a thorough medical training, under fully qualified Christian women, for those Christian women and girls who wish to prepare themselves for medical mission work." At the end of 1900 there

were 43 students on the rolls, or 15 less than in the previous year; of these 15 belonged to the Medical classes, five to the Compounders' classes, 7 to the Dais' classes, and the rest to the Nurses' classes.

Madras. The number of students at the Madras Medical College (including the School Department) during 1900–01 was 510, of whom 32 were women students. In the Hospital Assistant Department, consisting of 194 pupils, 45 appeared for the final examination and 31 passed, all in the second class. The results of the several University examinations in medicine were not so satisfactory, only 31 having passed out of 68 candidates entered, against 44 out of 66 in 1899. In the College Department there were 69 regular students, including three women students, reading for the M.B. and C.M. degree, 32 reading for the L.M.S. degree, and 20 casual students.

The only other medical school at work during the year was the Prince of Wales' Medical School, Tanjore. At this there were 29 pupils on the rolls, all of whom were being prepared for the Hospital Assistants' Certificate. Thirteen candidates appeared for the final examination and 5 passed.

Bombay The attendance at the Grant Medical College, Bombay, rose from 368 in 1899–1900 to 439 (including 31 women and 38 military pupils) in 1900–01. For the first University examination in medicine 175 candidates presented themselves, of whom only 98 qualified; and for the second examination in medicine only 54 passed out of 132 candidates. For the final examination for the degree of L.M.S there were 61 candidates, and of these only 22 passed.

The Government Medical Schools at Poona, Ahmedabad, and Hyderabad continued to work satisfactorily. The average number of students on the rolls was 235, and the results of the examinations were satisfactory.

VII.—SANITATION.

In Calcutta the improvement of bustees, or clusters of Native huts continued to receive attention. In the matter of water supply there is nothing to record but the ordinary working of the existing system. The average daily consumption of filtered water was 20,561,908 gallons, equal to over 24 gallons per head of the census population of 1901. The total length of filtered water mains and services amounted at the close of the year to 315 miles. A further advance was made during the year in increasing the supply of unfiltered water. The length of the unfiltered water mains and services in the town and added area at the close of the year was 156 miles. The consumption of unfiltered water was 13,109,390 gallons, against 9,687,500 gallons in the previous year; the daily consumption per head of population was over 15 gallons. Good progress was made during the year in the work connected with the sewage and storm water outfalls of the town and suburbs. Various reconstructions and improvements were made in the sewerage system which at the close of the year had a length of over 200 miles, and the number of premises connected with the system was 31,295, of which 625 connections were made during the year. The most important portions of the drainage schemes were held in abeyance owing to the Corporation having thought it necessary to refer the scheme to an English expert, Mr. Baldwin Latham. His report has since been received, and it is hoped that it will be speedily dealt with. **Bengal.**

The municipalities of the interior of Bengal spent £140,486 or nearly 45 per cent. of their income on sanitary works being an increase of about £12,000 on the expenditure of the previous year. In addition, various sanitary works were carried out by Municipalities and District Boards, by Government, and by private individuals at a total cost of £61,000.

The Sanitary Board held three meetings during the year, and continued as usual to advise the Government and local bodies on the important sanitary projects of the year. Among these were schemes for the improvement of the water supply of Manicktollah and South Suburban municipalities, and drainage projects for the important towns of Monghyr, Khulna, Dinajpore and Rangpur. Among the more important preliminary estimates prepared under the orders of the Board during the year were the Patna water works and a combined scheme for water supply to the riparian municipalities.

In the North-Western Provinces and Oudh nine towns, Agra, Allahabad, Benares, Cawnpore, Lucknow, Meerut, Mussoorie, Dehra Dun, and Naini Tal, are now furnished with waterworks and pumping machinery; these towns contain about one-third of the municipal population of the province. At Agra the water supply arrangements were further improved during the year; in Benares the large sewerage works were in progress, and measures were taken for the prevention of the pollution of the Ganges at the same place; and in Cawnpore an important scheme for the drainage and sewerage of the city was under consideration. Village sanitation books were introduced in 20 additional districts, making a total of 42 districts in which these books are now maintained. "A systematic record of the defects noticed and improvements made in the sanitation of towns and large villages cannot fail," it is observed, "to have a salutary effect." **North-Western Provinces and Oudh.**

The Sanitary Board met seven times in the course of the year when projects and estimates amounting to £14,000 for the improvement of the sanitation of municipalities were considered. The Board noticed with satisfaction the increased attention paid to the cleaning and protection of wells, and to the general improvement of the sanitary condition of the villages to which the Village Sanitation Act III of 1892 has been applied.

In the Punjab the municipal towns spent nearly 19 per cent. of their income on sanitation in the year 1900, or a little over 1 per cent. less than in the previous year. "In relation to sanitary progress generally," the Sanitary Commissioner states, "the province is improving. Endeavours are being made to supply every large town with a proper water supply and good drainage." **Punjab.**

Among the more important water supply and drainage schemes completed, in progress, or under consideration, were the extension of the Delhi waterworks, estimated to cost £12,000, the extension of the Simla waterworks scheme, and the improvement

of the water supply of Fort Dalipgarh in Bannu district. The water-supply scheme for the civil station of Dharmsala was still under consideration. Progress was made during the year with the Delhi drainage works, and, as far as completed, the drainage of the city is reported to be very satisfactory. The sewage works in Simla were well in hand; the drainage scheme for Fazilka in Ferozepore was progressing; and three separate projects for the improvement of the drainage of Lahore City were practically completed. Drainage works were also in progress in Rawalpindi, Hazro, and Abbottabad. The income derived from the sale of manure in all the municipal towns during the year amounted to £10,800 against £9,850 in 1899. Village sanitary note-books were in use in every district of the province, and they are reported to have proved useful. A new Sanitary Inspection note-book has been drawn up by the Sanitary Board.

The Sanitary Board held two meetings during the year when their attention was given to measures for the encouragement of improvements in village sanitation and matters in connection with the vital statistics of certain towns which have been supplied with drainage systems and waterworks, and where, *primâ facie*, improvement in the public health has not been exhibited. In the course of the year a sanitary engineer for the province was appointed.

Burma. No sanitary works of any importance were undertaken in Burma during the year 1900. The 41 municipal towns spent 55 per cent. of their income on sanitation, or 21 per cent. more than in the previous year. Prome was the only municipal town where anything appreciable was expended on water supply or drainage. Since the laying on of the river water, which is unfiltered, this town has greatly improved in health, and a system of drainage is now in progress. Schemes for the extension and improvement of the water supply of several towns were under consideration during the year, and that for Rangoon, which is estimated to cost about £73,000, was to be taken in hand without further delay. The Sanitary Engineer submitted water-supply schemes for several towns, chief among them being schemes for Moulmein, estimated to cost about £57,000, and for Meiktila; the drainage scheme for the latter has been completed. On rural sanitation a sum of over £12,000 was expended during the year from District Cess funds. The Sanitary Commissioner with the Government of India remarks: "While much actual achievement has not marked the year under review in regard to large sanitary works in either urban or rural areas, there is evidence of awakening on the part of the responsible authorities, and the next few years should see many useful and important projects completed."

Proposals for the re-organization of the Sanitary Board were submitted to Government during the year.

Central Provinces. The municipalities of the Central Provinces spent a little over 28 per cent. of their income on sanitation in the year under notice, or about 10 per cent. less than in 1899. This is hardly to be wondered at considering the terrible famine which prevailed throughout the province. Little was done in fact except what was accomplished in the way of improving the water supply by famine labour. The most important works in this direction were in Nagpur and Khandwa, in both of which places there was reason to fear that the supply of water might be insufficient. The Bhandara works were completed and progress was made with the Harda water-works.

Owing to the special circumstances of the year, no meetings of the Sanitary Board were held. "In several districts the work of Sanitary reform was," the Sanitary Commissioner observes, "on account of the general distress and consequent paucity of funds, much curtailed, while in some others it was brought to a standstill."

Assam. Excluding four towns which have no separate incomes of their own, the municipal authorities in Assam spent nearly 45 per cent. of their income on sanitation in the year 1900. No extensive sanitary work was undertaken during the year, and no provincial scheme of any importance was under consideration, but in almost all municipalities small sums were spent on improvements to the drainage and water supply systems. The sanitary improvements effected by Local Boards were chiefly in the direction of providing a purer water supply by the construction of masonry wells and the excavation of tanks at some of the larger villages. Sanitary inspection books were kept up in selected villages, but owing to a lack of interest in sanitary matters on the part of the village officials the books are in many cases of little value.

The Sanitary Board held three meetings during the year.

In Madras city a sum of £59,000 was expended on sanitation during the year, the chief item being £45,000 on miscellaneous sanitary works, while only £1,761 were spent on conservancy, and £1,454 on water supply. The Mylapore drainage system continued to give satisfaction, and progress was made with the new drainage scheme for the city during the year; the first two miles of the cast iron main were laid in the 1st Division. The work done by the incinerator corresponded closely with that in the previous year, and over 33,000 cartloads of rubbish were consumed. Two more incinerators were in progress. The quantity of water supplied from the Red Hills Lake was about 2 per cent. greater than in the previous year; but the level of the lake was lower at the close of the year than at the beginning; the lowest level (32·18) was in October. Madras.

In the Madras Presidency the district municipalities allotted about 60·6 per cent., and the district boards 5·3 per cent. of their income for sanitary purposes. A large portion of this expenditure was on conservancy, but the allotment out of municipal incomes for water supply altogether amounted to £40,260 in addition to that of Madras city. The Sanitary Commissioner reports that "the question of conservancy of towns is steadily receiving more attention from local bodies, whilst the various methods of biological purification of sewage are likely to become popular. The people, especially, realize the convenience of using household sewage filters." The programme of sanitary engineering for the year contained water-supply schemes for Berhampur, Tiruvannamalai, which were completed and submitted to Government, and for Negapatam and Calicut; and a drainage scheme for Madura. Besides these, plans and estimates were drawn up for schemes of water supply to five other towns and for the complete drainage of Ootacamund. Improvements to the Trichinopoly water supply were commenced and completed. The sanitary works undertaken and carried out by local boards during the year consisted in the sinking and repairing of wells, construction and repair of tanks, latrines, drains, &c., and the improvement of village sites and water supply generally. Village sanitary inspection books were in general use in nearly all the districts.

During the year the Sanitary Board scrutinized the plans and estimates of 108 sanitary works, 20 of which were for municipalities, 87 for Local Fund Boards, and one for the Public Works Department. The total estimated cost of these projects amounts to over £20,000.

In Bombay city the works executed or in progress in the Special Drainage Department during the years, included, amongst others, the ovoiding and constructing of masonry side drains, the construction of storm water drains in various parts of the city, and the construction of the Mazagon sectional sewerage works. The Corporation sanctioned the construction of certain works, to cost about £90,000, for the drainage of the lower parts of the city. Early in the year the Corporation passed a resolution expressing opinion that the work of house connections should be pushed on with as great a rapidity as may be compatible with efficiency, and the street portions of house drainage connections carried out numbered 6,002, at a cost of about £9,300. Although the rainfall at the Tansa lake was considerably greater than in the previous years, and the quantity of water received in the lake was much in excess, yet, owing to the early cessation of the rains, the lake fell to the lowest recorded level. The total number of water connections in the city was 20,394, of which 190 were made during the year. Bombay.

In the other municipalities of the Presidency about 21 per cent. of the income was spent on water supply, drainage and conservancy, and under the same heads the local boards spent 7 per cent. of their income. The large expenditure on plague precautions again checked the prosecution of sanitary works. The only works of any importance carried out were the enlargement of the Karachi waterworks and the deepening of the Pokhran tank in Thana, and of the Athin tank in Belgaum. The Bombay Village Sanitation Act was introduced into one other village during 1900, making a total of 301 villages now under its provisions. The Act provides for the establishment of a sanitary committee or a sanitary board, consisting of members chosen by the collector of the district or by the Local Government, to supervise sanitary matters; but it would appear that owing to famine and plague no progress was made during the year in the establishment of committees under this Act. Village sanitary inspection books were in use in 3,356 villages.

The Sanitary Board gave advice concerning several projects, including the Poona drainage and water supply projects, which were finally approved by the Government

of Bombay, and were before the Governmemt of India, as they involved the grant of loans on liberal terms to the local authorities. Plans for the Kaira and Mehmadabad water-supply schemes were prepared by the Board.

Berar. The municipalities of Berar spent 45 per cent. of their income on sanitary improvements in 1900. No new works of importance were in progress during the year, as expenditure on sanitary purposes had to be seriously curtailed owing to the cost of famine works and the adoption of preventive measures against plague. The District Sanitary Boards met once at each of the six headquarter stations during the year to take stock of the action taken on the suggestions made by the Sanitary Commissioner in his survey remarks on the several towns and villages surveyed in past years. Not much progress was made during the year in the sanitary survey of selected towns and large villages; no towns were surveyed, and only 135 villages. There still remain two towns and 3,981 villages to be surveyed.

India Office,
November, 1902.

ABSTRACTS

OF

SANITARY AND OTHER REPORTS

FOR

1900

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER WITH THE GOVERNMENT OF INDIA.

(*Surgeon-General B. Franklin, I.M.S.*)

European Troops.

Sickness and Mortality in 1900.—The health of the European army of India, though unfavourably affected as to mortality by the epidemic prevalence in India of cholera, bowel complaints, small-pox, and malaria, was as to sickness better than in the previous year; the increase in mortality and invaliding, however, somewhat outweighing the decrease in sickness.

Years.	Average Strength.*	Ratio per 1,000 of Strength.				
		Admissions into Hospital.	Constantly Sick.	Deaths.	Invaliding.	Total Loss.
1896–1900... ...	66,974	1,339	86	17·08	33	50
1899	67,697	1,149	73	12·75	32	45
1900	60,553	1,143	72	14·62	33	48
1891–1900... ...	68,224	1,399	87	16·21	29	45

*The quinquennial and decennial ratios are, of course, worked on the total strength of the lustrum and decade respectively.

The chief causes of admission were ague and venereal diseases. Among the diseases with increased admission rates were cholera, small-pox, and malarial fevers. On the other hand, the admission rates from influenza, respiratory affections, enteric fever, simple continued fever, and venereal diseases were lessened. Ague and venereal diseases caused respectively 27 and 26 per cent. of the total sickness.

The chief causes of death were enteric fever, and then hepatic abscess and cholera. Among the diseases with increased mortality were cholera, small-pox, malarial fevers, dysentery, diarrhœa, and hepatic abscess. On the other hand, the mortality from enteric fever and pneumonia was lessened. Enteric fever caused 33 per cent. of the total deaths, hepatic abscess 11 per cent., and cholera 10 per cent.

The chief causes of invaliding were, in order, syphilis and gonorrhœa, debility, malarial fevers, disordered action of the heart, tubercle of the lungs, and valvular disease of the heart.

The chief causes of admission in the China Field Force were ague, dysentery, venereal disease, and diarrhœa, and the chief causes of death enteric fever and dysentery.

Commands.—In the following table the ratios of the four commands are placed side by side for comparison. Madras was the most unhealthy of the four commands, Bombay coming next, and both being more unhealthy than in 1899. Bengal had the highest mortality from tubercle of the lungs, dysentery, and abscess of the liver; the Punjab from remittent fever, heatstroke, and pneumonia; Madras from cholera, ague, and dysentery; Bombay from small-pox, enteric fever, and diarrhœa.

Stations.—The highest death-rates among stations of over 100 strength were those of Fort Lahore, Barrackpore, Delhi, Neemuch, and Nasirabad; and the highest among stations of over 1,000 strength those of Secunderabad, Meerut, and Mhow. In all these stations cholera was a factor in the mortality. In addition there were high ratios at Barrackpore from hepatic abscess, dysentery, and enteric fever; at Delhi and Neemuch from enteric fever and dysentery; and at Nasirabad, Secunderabad, Meerut, and Mhow from enteric fever. All the stations mentioned had greater mortality than in 1899.

Geographical Groups.—The following table shows that, judging by the constantly sick rate, Gangetic Plain and Central India were the most unhealthy groups for the decennium, and the Hills and Western Coast the most healthy. The highest decennial admission ratio for cholera was in the Gangetic Plain, for enteric fever in the Hills, for ague in Indus Valley, for pneumonia in Indus Valley, and for dysentery in Bengal-Orissa. Only for dysentery was the relation the same in 1900. An examination of the figures of the longer period for European troops, native troops, and prisoners, shows that for all three influenza was least in Western Coast, ague in Southern India, venereal disease in Indus Valley; and small-pox most in the Deccan, pneumonia in Indus Valley, and dysentery in Assam and Bengal-Orissa.

Influenza.—The absolute and proportional amounts of influenza fell greatly. The admissions, which had fallen at the end of 1899, began to rise in February, reached a maximum in June and a second, somewhat higher, in September, and then fell to the end of the year. The first epidemic year was 1890. The actual maximum of the individual years of the eleven occurred in various different months, but over the eleven year period as a whole the greatest numbers of cases occurred in April and March, and the smallest numbers in August and September. Groups IV, VIII, and X were affected in 1900, but not in 1899; while Groups II and VII, which had been affected in 1899, escaped in 1900. The other groups containing British troops were affected in both years. Twenty-two stations returned cases against twenty-eight. The highest numbers were at Barrackpore, Dum-Dum, and Lucknow. In Barrackpore the disease attacked only the British troops, was severe in type, sometimes resembling scarlet fever, often left behind great prostration, caused two men to be invalided, and in two cases was followed by abscess of the liver.

Cholera.—The amount and proportion of cholera was much greater than in the previous year, the admissions having risen from 1 to 107. At Secunderabad, where the highest number of cases occurred, cholera was prevailing in the city and surrounding villages almost as soon as the monsoon began; and, though all infected places were put out of bounds, and native cooks dismissed, cholera of a virulent type attacked all the corps in barracks, except the Artillery, of which, however, two men in hospital were attacked. In the case of the other stations also with comparatively high numbers, it is mentioned that the disease was prevalent in the civil population; and it is believed that but for the precautions taken, the troops would have suffered more severely. Some of the famine tracts were areas of special danger. The ratios were less than in the native troops and prisoners. Four (non-fatal) cases of "epidemic diarrhœa" were returned from a cholera camp at Shalimar, near Lahore and Meean Meer.

Small-pox.—The admission rate from small-pox was three, and the death-rate five times greater than in the preceding year; and the admissions and deaths were 36 and 3 against 14 and 1. The disease was prevalent in the country, and here, again, the influence of the famine was unfavourable. The highest number of cases was 10 at Kamptee. No other station had more than 3 cases, and no station had more than one death. The Deccan had most small-pox.

Ague, remittent fever, simple continued fever.—Ague gave rise to nearly 27 per cent. of the admissions from all causes. Both the admission and the death-rates were raised, and the increase, where it was greatest, was usually ascribed to unusual rainfall and floods. The greatest outbreaks were those at Ferozepore and Fort Dufferin (Mandalay). At Ferozepore the increase, gradual at first, became explosively sudden in October, and the type of the disease altered for the worse, many of the patients exhibiting alarming symptoms, though few died. At the same time mosquitoes were unusually abundant and troublesome, and *anopheles* was found in barracks, bungalows, and hospital. The women, children, and bandsmen returning from the hills were all attacked; and from their cases it was judged that the incubation period of the disease is about 14 days. The whole wing of the Oxford Light Infantry had to be sent to Kurrachee* for change of air, being completely prostrated and incapacitated for duty. The other classes of the population also suffered. At Mandalay the men of the 2nd Durham Light Infantry, stationed within the walls of Fort Dufferin, suffered severely, while the artillery, stationed near Mandalay Hill, were "practically free." This is said to be due to the infantry barracks being situated in a marsh, not capable of being rendered habitable by drainage, "a locality so notoriously unhealthy that in King Thebaw's time the place was abandoned by the Burmese." About 350 men of the regiment had to be sent away to healthy stations for change, and at last the regiment had to be sent out of the country to Wellington. Some of the troops at Aden had come from malarious stations in India, but the Isthmus Position was considered to be an undoubted local source of malaria, especially after a heavy rainfall in February, and had to be evacuated for the second time in ten years with good effect to the health of the men. It is said to be low and damp, so that one inch of rain is enough to turn it into a marsh. The finding of *anopheles* was recorded also at Delhi, Roorkee, Agra and Deesa On the other hand, it is said to have been rare at Rawalpindi, and not to have been found at Colaba, though it is stated that it is common in some other parts of Bombay, especially Malabar Hill; and in the room at Bangalore, occupied by the company chiefly affected,

* This, of course, affected unfavourably the health statistics of Kurrachee.

only *culex* could be discovered. In the hospital at Nowgong two cases of fresh infection occurred in a ward on the ground floor. In front of the ward there was a small masonry tank, from which the garden was watered, and this was found to be a haunt of *anopheles*. The tank was cleared out, and the patients removed to the upper floor, and no further cases occurred in hospital. The prophylactic use of quinine was found disappointing at Ferozepore, Mandalay, and Nasirabad; of doubtful benefit at four stations; but good at nine. In cases of apparent failure, present knowledge would indicate, not the stoppage of the issue, but an endeavour to find the cause of the failure, so that it might, if possible, be removed or avoided.

There was also, naturally, an increase in remittent fever. The monthly distribution was not quite the same as that of ague, but there seems no reason to doubt the correctness of the opinion of medical officers that in most cases the disease was malarial. The highest numbers were at Fort William, Peshawar, and Rawalpindi. There were no cases in the Ferozepore malarial outbreak, described above, and only 11, none fatal, at Mandalay.

There was a reduction in simple continued fever. The most frequent causes assigned for the attacks were high air temperature, exposure to the sun, especially if combined with fatigue, digestive derangements, and chills. Any definite fever which seemed to be neither malarial nor enteric was so returned. It was suspected that some cases might have been mild enteric fever or influenza; and some of the cases at Calcutta suggested Malta fever, though no case of Malta fever was returned anywhere in India. The probability was entertained that some cases were really malarial, and the rise in October seems to support this idea. The results of post-mortem examination in the two fatal cases did not show that any error in diagnosis had been committed; and the deaths were considered to have been accelerated by the very high atmospheric temperature prevailing at the time. A re-action, supported to some extent by the results of serum testing, has set in against the extreme opinion that all cases of so-called simple continued fever are in reality cases of enteric fever.

Enteric Fever.

Water and the Bacillary Diagnosis in general. Filters, &c. Milk.—The riddle of the exact relation between the enteric and the colon bacilli is still unread; and, therefore, the bacteriological examination of water, among other things, is still in a state of uncertainty. Houston appears to think it safer in the meantime to acknowledge as enteric only those bacilli which respond to all the known bacteriological tests; while Chantemesse, Rémy, and others, have shown reason for believing that the enteric bacillus living in association with other micro-organisms may lose certain of its classical characters, but most frequently its specific agglutinating power; and it is not infrequent in the reports of water examinations to read of suspected bacilli which answered to all or nearly all the tests except the serum one. To show, according to Rémy, that a bacillus giving the cultural characters of the enteric bacillus, but failing to stand the agglutination test, is really the enteric bacillus, it is necessary to inoculate it into a guinea pig, and then with the serum of the animal to obtain the required specific re-action with an authentic culture of the enteric bacillus. Horrocks, on the other hand, in describing the discovery in water of coliform bacilli which could hardly be distinguished from the enteric bacillus by cultivation, but refused agglutination, states his opinion, one somewhat widely held, that a bacillus not agglutinated is certainly not enteric, but that a bacillus agglutinated by a moderately dilute serum is not necessarily enteric; while Houston has isolated from water a few colilike microbes, which were certainly not *Bacillus typhosus* and could not be classed as *Bacillus enteritidis*, yet which clumped in marked fashion with one or other or both sera. Again, Houston agrees with Horton Smith as to the fallacy of considering an unknown bacillus as Eberthian simply because it responds to the agglutination phenomenon, without seeing whether it answers to other tests for the typhoid bacillus; and Sternberg is of the same opinion, and also Hunter and Köhler and Scheffler. In view of the difficulty of separating the enteric from the colon bacillus, new processes are continually being devised. Cambier and also Gabritschewsky attempt to attain the end desired by utilising the greater motility of the enteric bacillus; while, with special reference to water, Chantemesse has introduced a method which consists in collecting the microbes from a considerable quantity of water, and then using an enrichment process. Others, despairing of being able to isolate small quantities of the microbe diffused in immense masses of water, have endeavoured to ascertain what commoner microbes might be regarded, when found in water, as signs of fæcal pollution. This matter has been referred to in former reports. In answer to the query whether the presence of the colon bacillus in water taken from a well

15 feet deep would justify one in stating in court that this was evidence of contamination by excreta, the *British Medical Journal* replied that no categorical answer could be given ; that the bacillus coli is an excremental organism, but is so ubiquitous that the reply must depend on the number of bacilli present, that is in what minimal quantity of the water at least one representative of the *B. coli* is present ; that if in the well in question the *B. coli* is found in 10 c. c. of the water or less, it is evidence of contamination, if in 10-50, contamination is dubious, if only in over 50 c. c., it is devoid of significance ; but that much depends on the method adopted for its detection. But Parkes declares that any sample which contains the colon bacillus in 50 c. c. should be condemned ; while Weissenfeld asserts that the colon bacillus is not characteristic for the fæces of men and animals, and will be found present in all water, if enough is examined. By an ingenious application of his own observations Horrocks seeks to get over the difficulty. He found that as regards reaction to antityphoid horse serum the varieties of the colon bacillus isolated from typhoid stools showed much greater sensibility to agglutination than the varieties of the same bacillus isolated from healthy stools ; and therefrom draws the conclusion that if varieties of the colon bacillus isolated from a water-supply are found to be agglutinated by antityphoid horse serum in 1·500 dilution, there appear to be reasonable grounds for the assumption that the water-supply in question has been fouled with specific dejecta from cases of enteric fever. The success of this test would probably depend on the length of time the bacilli had been in the water. The whole subject is lucidly reviewed by Houston. In India the opinion of Hankin is well known, that pure water, from the absence of competition, suits the enteric bacillus, and that the infection of a pure water-supply is therefore particularly dangerous ; and Wanklyn has stated that the most dangerous water is one highly charged with organic matter, but almost free from organisms. So, Johnston mentions, that Jordan of Chicago has kept the enteric bacillus alive for 93 days in sterilized Lake Michigan water. Again, Groves quotes Frankland's experiments in which the enteric bacillus ceased to be infective in 5 days in river water which contained millions of organisms in the c. c., but remained infective after 35 days in deep well chalk water containing less than 150 in the c. c. Houston mentions that while most continental observers are of opinion that the typhoid bacillus loses its vitality somewhat rapidly in unsterilized potable waters, Klein's results indicate that the distinction has been overlooked between a great decrease in number and total disappearance. By paying attention to this point Klein was able to show that some typhoid bacilli persisted in unsterilized water long after the majority had perished. Cases in which the infection seems to have survived travel in the volume of a river in company with other microbes and to have then originated outbreaks in towns miles down the river have been reported by Fosbroke at the Cheltenham meeting of the British Medical Association, and by Jownston, Mills, and others at the Michigan Conference of Medical Officers of Health. Besides detailing the proofs that the infection was so carried down stream, Johnston states that the Massachusetts Board of Health took Merrimac River water and experimented with it, and found that typhoid germs would live in it 25 days, long enough for them to be carried 685 miles down the Merrimac River. And Mills remarks that hitherto it has been taken for granted that polluted water poured into a running stream becomes purified within a short period of time : but that this is now questioned, and it is believed by many that the germs of typhoid fever have been carried long distances by flowing streams, as from Port Huron to Detroit, a distance of 60 miles. Some new instances have occurred of the use to which the purposive or accidental admixture of yeast, absinthe, or fluoresceine has been put for the detection of the source or course of a water. The *British Medical Journal* in a leading article on the Waste of Life and Efficiency in South Africa remarks that the exact proportion between waterborne infection and infection by other means—infected dust clouds, flies, &c.—cannot be stated, but that, as a working and probable hypothesis, it might be assumed that in half the cases the infection is waterborne ; that in one-fourth it is carried by specifically contaminated dust or by flies ; and that in another fourth there is direct personal infection. Again at the Michigan Conference, Riggs brought forward the statistics of the alleged causation of 31,264 cases of enteric fever, derived from the reports of the Michigan State Board for 10 years, and after studying them, concluded by saying that he believed that a careful study of the disease based on full and complete reports would show that 90 per cent. of all cases are directly or indirectly traceable to contaminated water, and that a further analysis would trace the source of this contamination to sewage, garbage, cesspools, &c. ; and in this connexion it may be pointed out that Parkes and Kenwood, in noticing Klein's results as to the very

favourable medium which nitrate sewage presents to the enteric bacillus, remark that crude sewage is, as a rule, free from nitrates, whilst sewage that has been filtered through soil contains nitrates as a result of oxidation, which may be the reason why well-waters polluted by drain or cesspool leakage through the soil have the capacity, apparently, of retaining for considerable periods the infective properties introduced by the specific pollution. Leigh Canney in polemical writings or papers has contended for the supreme pre-eminence of water as the vehicle of the infection; and believes that enteric fever will have to be met and overcome, in no matter what part of the world, on the waterborne theory mainly, though without neglecting other avenues of infection. On the other hand, Professor Victor Vaughan, at the Michigan Conference at Grand Rapids, stated that he had been in the habit of saying to his students, until a year ago, that 90 per cent. of the cases of enteric fever were through infected water, but that he would not say so now; he believed that enteric fever in civil life is largely disseminated through the drinking water; but in military life it is often spread by other means, such as dust and flies. Washbourne agrees with Canney that epidemics of enteric fever are waterborne and not airborne, but believes that sporadic individual cases are infected otherwise than by water. So, Barr remarks that pure water-supply has abolished widespread epidemics; but that as an endemic, enteric fever is as prevalent and of as severe a type as it was a quarter of a century ago; and Parkes and Kenwood that it is the experience of numerous places that enteric fever may be endemic, notwithstanding a water-supply of undoubted purity. With regard to India it may be said that the medical officers on the spot seldom believe in any exclusive water theory, and that they have advanced good grounds for their opinions. As to filtration, Fuller, the New York Consulting Expert, insists that it is of prime importance to know the individuality of a water as a first step towards its successful purification, in order that the processes associated with filtration, such as storage, subsidence, coagulation, and aëration, may be properly considered. Houston reminded his hearers that though efficient sand filtration is a great safeguard, there is no reliable evidence to show that it more than greatly lessens the danger; and that filters on the small scale are usually untrustworthy. Horrocks states that if there are no flaws, the enteric bacillus cannot get through the walls of the Pasteur-Chamberland filter; but that it can get through the Berkefeld in from 4 to 11 days, so that the candles have to be boiled every third day. Munson's opinion that both the Berkefeld and the Pasteur-Chamberland filters, if given proper care, serve an excellent purpose in fixed camps or garrisons, but that the difficulties attending their liability to clog or break and the necessary periodic sterilization are such as to render them often a trouble rather than an advantage in the field, is confirmed by experience; but even in fixed sites, such is the care required that they are sometimes not a success. The Waterhouse-Forbes water sterilizer is described by Munson, who considers it the best form of heating sterilizer. It was favourably reported on in America by a board, which found that a single apparatus would suffice for the needs of two companies, or, where storage of water was possible, of a battalion; and also at Netley. It may be of interest to note that the frequently extolled Schumburg bromine process is reported by Schüder to be unable to accomplish the destruction of the enteric bacillus in water.

Klein has shown that milk is a better medium for the enteric bacillus than cream, and cream than cheese.

Soil, dust, flies, direct infection.—S. Martin continuing his experiments under circumstances more favourable to the microbe than before, found that the enteric bacillus died out in unsterilized soil within 12 days, owing to the antagonism of the soil micro-organisms. Mentioning these results and taking into consideration some of his own, Houston comes to the conclusion that surface soil is unfavourable to the growth and vitality of non-sporing microbes of intestinal origin, though he desires to speak with great caution on the subject, in view of the puzzling features connected with the endemic and epidemic prevalence of enteric fever in certain localities. Rullmann was able to recover the enteric bacillus from unsterilized earth after 100 days, and notes that the length of survival depends on the chemical composition of the soil. Vaughan is of opinion that the German experiments prove that the bacillus can be destroyed by drying, but not that the disease is not airborne or may not be so, and gives some practical reasons for believing that it is spread in this way; and Tooth, Church, Chiene, and others were impressed with the probability of this mode of dissemination in South Africa; but Sir Charles Cameron appears to be alone in thinking that it may almost be said that the disease is generally airborne. Houston, on the other hand, finds it difficult to believe that a non-sporing bacillus of comparatively speaking delicate sort can remain dormant for

long periods, neither multiplying nor dying, in the form of dust ; though he agrees that excreta and particles of soil and the fluff of soiled linen may, when the specific contamination is comparatively recent, be brought into relation with articles of food or drink in the form of dust. A very interesting observation is recorded by Vaughan, in which when lime had been sprinkled over the contents of the latrines, a short time afterwards flies could be seen with lime on their feet crawling over the potatoes or meat and bread that the men were going to eat ; and Simons quotes another American case in which the use or non-use by three bodies of men of fly-proof cages for their provisions, seemed to determine attack or non-attack ; and relates an experience of his own in which soil specific contamination acted directly in the winter and by means of flies in summer. Finally, Howard in America found that it is only diptera which go to human excrement, in all 77 kinds, of which 36 feed upon it. It appears to be generally acknowledged that the disease is frequently communicated by personal intercourse, and fresh instances have been adduced by S. Murphy, Handford, Gualdi, Kruse, and Guinon. Vaughan says that it can be carried on the hands, under the finger nails, in the clothes or blankets, and impresses upon his hearers that it is a "fearfully infectious disease" ; and Houston that it needs to be remembered that the direct spread of infection from the sick to the healthy is no idle myth but a dangerous fact.

Urine and urotropine. Sputum.—It has been mentioned in former reports that the bacillus appears in the urine in about 25 per cent. of cases. In 12 cases Neufeld found the same proportion,* and observed the sudden onset of the bacilluria marked by clouding of the urine. Houston, while believing that the potentialities for evil of a convalescent with specific bacilluria are so great as to be almost inconceivable, and accepting the fact that a case may for months or even years be a manufactory and distributory of the morbific virus of the disease, a fact which may explain some puzzling features in the spread of the disease, is struck by the difficulty† of understanding why some places, after being visited by severe epidemic, may remain for long periods afterwards almost free from the disease, notwithstanding that probably many of the inhabitants are carrying about within their bodies the living germs of the disease, and that some of them are possibly discharging enteric bacilli broadcast in their urine. Handford has suggested that the bacilli excreted in the urine may not always be in a virulent condition. In a case of cystitis caused by enteric bacilli that had come from the kidney, Curschmann found that the bacilli excreted in the urine, so far as could be judged by agglutination, were not reduced in virulence. The routine exhibition of urotropine (see former reports) is advocated by Houston, as by Richardson, Horton Smith, Clifford Allbutt, and others ; but there are certain drawbacks to its use. For, while at least five cases of hæmaturia from its use have been reported, and Neufeld confirms the fact that the bacilluria is apt to recur, Schumburg states that the drug merely inhibits the bacillus, which can be found in a condition capable of activity in the urine cleared by the use of urotropine, and concludes that the urine voided by the patient should be disinfected with mercury perchloride. It is in cases with pneumonic complication, while the expectoration is coloured by blood, that the bacillus has been found in the sputum. Its presence may persist into convalescence, so that a man may be dangerous to others after he has apparently recovered.

Sewer air. Sewage. Nitrate sewage.—The investigations of Lewis and of Andrewes and Lawes have shown that sewer air and foul emanations from cesspools have probably no part in the direct conveyance of the fever. The search for the enteric bacillus in sewage is acknowledged to be almost hopeless ; but Houston has pointed out that, judging from the behaviour of other microbes which can be more easily isolated from sewage, there can as yet be no confidence felt that the enteric bacillus may not be contained in sewage effluent from biological process tanks. When the enteric bacillus is planted in sewage to which 1 per cent. of potassium nitrate has been added, it retains its vitality for a considerable period, and undergoes rapid and continuous multiplication. In media containing 4-5 per cent. of nitrate the enteric microbe is reported to grow almost like a blastomyces.

Non-Eberthian fevers. Widal's test. Enteric fever without intestinal lesions. The bacillus in the blood.—The occurrence of non-Eberthian enteric fever has long been suspected or recognised. Cases have been quoted in former reports, and the views of

---

*, Schüder in D. M. W. XXVII, page 762, reports five out of 22 ; and shows that for all examined and recorded cases the percentage is something under 30.

† See also Neumann in D. M. W. XXVII, page 769.

Durham were given on page 26 of that for 1897. Petruschky refers such cases to members of the coli group. Some fresh cases have been reported, by Firth in India, and by Kurth and Schottmüller in Germany. The morbific agents in Firth's cases were the bacillus of Gärtner and members of the coli group, in Kurth's bacilli differing from those of Eberth and of Gärtner, and in Schottmüller's a bacillus standing between the enteric and the colon bacilli. Such cases, if not recognised, might, of course, contribute to the number clinically diagnosed which fail to react, or react irregularly, with Widal's test. But the test may fail also when typical lesions are present, or when the bacillus of Eberth is found in the blood or organs, and it is occasionally positive in the absence of Eberth's bacillus. And Koch has lately acknowledged that the reaction is not absolutely specific. However, it is rumoured that he will shortly bring forward a new test for the presence of genuine Eberthian fever. Fresh cases without intestinal lesions have been reported by Stewart, Lazarus-Barlow, Weichardt, Guizzetti, and Barjon and Lesieur ; but the best recent commentary on the whole subject is that of Opie and Bassett, who, though unable to deny that enteric fever may occur without intestinal lesions of the intestine, consider much of the evidence furnished by the published reports as inconclusive. The case which led to their remarks did not run its course without intestinal lesions, but the circumstances were such as might have led less careful observers to return it as one without intestinal lesions. They point out that the Peyerian swelling probably frequently subsides without going on to ulceration, and that cases in which death occurs early in the disease can alone furnish conclusive evidence that lesions of the intestine have not been present. As the result of the examination of 15 cases Cole concludes that it is apparent that enteric bacilli occur in the blood with much greater frequency and during a much longer time through the course of the disease than was formerly supposed, and in six the bacilli were found in the blood before Widal's reaction was present. The results of Scholtz and Krause were similar. Others have also been successful in cultivating the bacillus from the blood and the roseola.

Prevention ; Inoculation.—As Houston remarks, the greater our knowledge of the channels of infection and modes of dissemination of the disease, the greater becomes the probability of preventive treatment ; the measures of prevention being vaccination, early diagnosis by means of Widal's test, protection of water-supplies and sterilization, filtration, etc. ; shielding all articles of food from objectionable contamination ; keeping conservancy, sewers, and drains in good order ; disinfection of the stools, urine, and soiled linen of enteric fever patients ; early recognition of bacilluria and exhibition of urotropine, which must have a most important influence in the future in controlling the spread of the disease. As Duclaux well says, the enteric bacillus becomes difficult of recognition once it has escaped into outer nature, and it is far better to destroy it when it leaves the body than to wait till it gets into the water. The opinions of medical officers as to the prophylactic results of inoculation are conflicting, and there are various difficulties in the way of obtaining, or obtaining at once, the accurate statistics required for the formation of a legitimate conclusion. Some of the unfavourable results may have been due to ignorance of the fact, which Wright has just discovered and published, that when the reaction produced in the subject of inoculation is very marked, there is at first an increased liability to enteric fever ; so that when enteric fever is prevalent, small doses should be used and mild reaction aimed at. The prophylaxis of enteric fever has been treated of in detail by Schjerning, Vaughan, and Munson.

Opinions of Medical Officers.—As was to be expected, a number of medical officers attribute the diminution of enteric fever to the absence of drafts from England, owing to the South African war. In a few cases it is stated that particular barracks or corps were more affected than others, or that the disease was equally distributed among them ; but in the majority of instances they appeared to be affected indiscriminately. At Agra 10 out of 19 came from two barracks that showed want of supervision and cleanliness, and little attention to the boiling and pinking of the water. No reason could be discovered at Nasirabad why, though cases came from nearly every barrack, eighteen came from numbers 12 and 18. Nowgong's cases were all in the North Staffordshire Regiment ; and none occurred in the battery, which had been longer in India, and had already suffered severely in 1898. Enteric fever at Thobba was confined to the Bedfordshire Regiment, which had rested one day at the Meean Meer Rest Camp, where the water was reported to be open to filthy pollution. At Aden the disease was almost confined to the Royal West Kent Regiment in the Crater Position, and this was considered to be due to the fact that that position was much more exposed to dust than Steamer Point. As usual, many cases had not been contracted in the stations in which

they were treated; and not infrequently, especially with cases in the Hill Stations, the infection had been acquired on the march. In many cases the origin of illness was ascribed to the partaking of unauthorised or unselected food and water at stalls, tea-houses, and refreshment rooms in the bazaars, cities, or villages; at segregation, rest, or practice camps; at manœuvres or on the rifle range; when out walking, shooting, climbing khuds, travelling by railway. Dirty irrigation channels are one of the dangerous sources mentioned. One case in the Dagshai military prison (a man who had been 125 days in confinement) was traced to the use of a dirty surahi; one man was believed to have ingested the infection by swallowing water while bathing in a dirty tank; another had been eating watercress bought from natives; while in two stations it is mentioned that men attacked had consumed unauthorised water because they objected to the taste or to the want of coolness of the boiled water. It is reported that the first six cases at Quetta appeared in the fife and drum band of the Wiltshire Regiment, after a big Christmas dinner, most of the food and drinks for which had been bought in the bazaar. At Dagshai two men were supposed to have got the fever through milk purchased from a filthy hawker; the Kasauli dairy was reported to possess every possible defect from a sanitary point of view; while with regard to Subathu it is stated that on the 10th May all milk was ordered to be boiled, and that the epidemic ceased within 14 days. Other sources of the disease were believed to have been—the occupation of contaminated sites; specific inoculation of the trenches by post-mortem washings or by the stools of ambulant cases, especially when the trenches were to windward and, from want of water, were not cultivated; the distribution of dust from such places by the wind; the laying down of dirty river sand in the horse lines, and carelessness in the protection of drinking-water there and elsewhere; insufficient conservancy staff, resulting in want of promptitude and completeness in the disposal of nightsoil; neglect, and consequent uncleanliness, of barrack cisterns; the use of specifically polluted municipal water for the manufacture of aërated waters in the city, while the troops were intended to get only specially protected and treated well-water; the use of leather pakhals; bhistis taking impure water from roadside pools and horse-ponds. Men were supposed to have been rendered more liable by exposure to sun, heat, bad drainage, &c., or by diseases that arise therefrom, such as simple continued fever and tonsilitis. In some instances it seemed clear that the first case or cases were imported. Among the circumstances from which *patients* dated their illness were overexertion, overheating, oversunning, fatigue, and chill from field days and manœuvres, or from bicycling; a long journey by train; getting wet and sitting in wet clothes; bad cooking or bad food; bad smells from latrines or gardens; getting food or drink from hawkers or in the bazaar; swallowing dirty water while bathing in a buffalo-tank; nursing a case of enteric fever. The medical officer in charge at Lucknow cannot understand why there should be little difference in the enteric fever ratio, though a fifth of the men were inoculated, though no drafts arrived from home, and though many men had been sent to the hills before the enteric fever season; and from Nasirabad his complaint is echoed. On the other hand, the comparative immunity of Wellington and Mandalay could not be explained, especially as in the latter the water-supply was bad and very liable to pollution. Fifteen medical officers ascribed the reduction in enteric fever to the absence or smallness of drafts, and one to the large number of young men sent to the hills early in the year, while one notes that the men, retained in India, had become more acclimatized. At Subathu the good new water-supply gets the credit. By various medical officers some of the following measures were believed to have been effectual—douching the latrines twice daily for a fortnight with perchloride of mercury; treating the wells, latrines, and urinals with permanganate of potassium and hydrochloric acid; cleansing cooking vessels and mussacks with potassium permanganate every morning; mounding the night-soil, and using it to manure india-rubber trees; closing manure and nightsoil depôts that lay to windward; discontinuing sewage irrigation; avoiding as much as possible the use of barracks that had given most cases in previous years; putting the bazaar out of bounds (Umballa, Poona, Nasirabad, Neemuch); using Pasteur filters; boiling or pasteurizing the milk; on receipt of enteric convalescents from another station, keeping them to a separate latrine and destroying their stools and urine by fire. The presence of a number of men inoculated is also mentioned as a possible factor in reduction. Some officers speak of a lower degree of heat, and of fewer flies and less dust in consequence of thunder storms. Bringing the troops up earlier in the year than usual was thought to have had a good effect at Chakrata and Landour. At Raniket there were no convalescents, fewer young men, cooler air, fewer flies, and less dust; while at Chakrata the garrison came up earlier than usual, contained fewer young men, and had marched from the plains by a new

route, thereby avoiding the suspected camps and wells of the old route, and used barracks and latrine to which special attention had been given. The dryness of the year and the saltness of the soil are mentioned at Kurrachee, but it is doubtful whether either of these would really have a favourable effect. The use of Widal's test is said to have reduced the number of cases to be returned as enteric fever. One medical officer thought that the stopping of pinking and boiling conduced to reduction of the disease, apparently because the water was less handled. The water-supply of four or five stations is distinctly stated not to have been concerned in the origin or spread of the disease. At Lucknow, Agra, and Kurrachee the intake of the water was not sufficiently protected; at Umballa, Meiktila, Mandalay, and Shwebo the water was very liable to contamination; at Poona distribution, treatment, and storage were all defective, and to the canal which brings the Poona water natives had free access in places, and could be seen washing themselves and their clothes in it; at Ahmednagar and Nasirabad the supply was deficient, as well as liable to pollution; at Kurrachee the pressure was insufficient, so that men got into the habit of keeping a receptacle below the tap, and dipping their vessels into that; at Roorkee the water contained excess of chlorides from having passed through polluted soil; at Agra the soldiers could get the bad municipal water in the city, though not in cantonments; at Nowgong and Agra, respectively, the dairy well and a sanitary camp well were found to be in an unsatisfactory condition; at a few stations pakhals were still in use; at some stations, such as Calcutta, Fort Allahabad, Agra, Madras, Wellington, Secunderabad, Thayetmyo, Nasirabad, and Aden, there was a double water-supply, one for drinking, and one for other purposes. Of the fifteen stations which mention the carrying out of water analysis, eight return the result as good, bacteriologically good, or chemically and bacteriologically good. The water at Quetta was found to be originally very pure, but a bacteriological examination, not completed at the time of report, suggested that contamination possibly took place in barracks, from leaky pipes. In the water of Roorkee and Nasirabad there was excess of chlorides. "A" Spring at Chakrata yielded the colon bacillus in August and November; and an enteric-like bacillus was found by Mr. Hankin in a specimen of the Baircha water from Mhow. The Chemical Examiner for Burma did not consider the Meiktila lake water fit for drinking purposes, and Captain Rost, I. M. S., is said to have isolated the enteric bacillus from it. At Agra the water was examined weekly by Mr. Hankin, who found the enteric bacillus in samples from No. 43 standpost and from the river Jumna in May, in a sample from number No. 43 standpost in July, and in a sample from No. 53 standpost in November, though in the last two instances the microbe reacted but feebly with serum. In 25 other samples of Agra water there was found a bacillus having many of the cultural characters of the enteric bacillus, but which did not react to the specific serum, and gave a yellow growth on potato. No enteric or enteric-like bacilli were found in wells Nos. 4 and 5 in the British Infantry lines, the wells from which the drinking water for the troops was drawn. No system of purification of water was employed at Barrackpore, Dagshai, and Rawalpindi; Peshawar used the Pasteur filter; but in most stations the water was subjected to the action of boiling, potassium permanganate, or alum, each process alone or in combination with one or both of the others. In a few stations stress was laid upon the danger of contamination from handling during or after the process; but this danger is minimised wherever the Larymore boiler and its accessories are introduced. In some aërated water factories great care was observed, not only with regard to the water to be aërated, but also with regard to the cleansing of the bottles with permanganated water, acidulated water, boiled water. It has not been possible to obtain correct statistics whereby to compare the incidence of enteric fever on total abstainers with that on non-abstainers. A few of the men attacked stated that they never drank plain water; and about 170 never drank milk, about 30 not even in their tea. At Quetta all enteric stools have for two years been destroyed by fire; and in the reports of several other stations similar destructions of the fæces or of the fæces and urine is mentioned: and, as all stations possess the means to do so, the process has probably been carried out in many unreported cases. From a few stations it is reported that the men have begun to do their own cooking. Several medical officers were convinced that flies were important agents in the dissemination of the disease. Thus, from Mhow it is reported that flies were very numerous, that ambulant cases of enteric fever occurred, and that the filth carts were not properly cleaned from want of water. Dust and duststorms were considered to have been spreaders of the disease in several stations, perhaps most especially at Aden and Quetta. The medical officer at Quetta is of opinion that efficient watering of the roads would do much to check the extension of the disease. On the other hand, it is pointed out that at Nasirabad there were no cases in June though duststorms occurred, while there were cases in

September in the absence of duststorms. In a good many hospitals the serum reaction of patients was tested, at some stations more systematically than at others, every case at Kasauli, for example, in the latter part of the season, that lasted more than two days being thus tested. In many cases both enteric fever and Malta fever were tested for. Cases reacting negatively were often put down as simple continued or as remittent fever, though in a few cases the diagnosis remained enteric fever. At Jubbulpore there appears to have been a case without intestinal lesions, and another in which there were only two small ulcers in the caecum. In nine cases enteric fever and dysentery were concurrent or closely connected in time of occurrence. In the Murree case the patient was convalescent from enteric fever, when dysentery developed, and was followed by abscess of the liver. At Chakrata abscess of the liver followed enteric fever in one case. Out of the 970 cases of enteric fever which occurred throughout the army of India in 1900, 27 are noticed as having declared themselves among patients in hospital or among attendants. Out of these, 8 were in hospital for early venereal disease (the secondary symptoms in one case running concurrently with the enteric fever); and 12 for other diseases; and 7 were attendants on enteric fever cases. Two men at Quetta suffered from second attacks, the first attacks having been in 1898; while at Chakrata one man is said to have suffered from his third attack in three successive years. At Khyragully, it is reported, one native follower suffered, and another who nursed him also contracted the disease, both recovering. The serum test appears to have been frequently used in the diagnosis of cases.

Enteric Fever in 1900.—There was again a great decrease of both morbidity and mortality from enteric fever. The admission ratio was the lowest that had been seen since that of 1888, though higher than in any of the years before that except 1886. Of the causes of decrease already mentioned probably the most powerful were the almost complete absence of drafts from England and the freedom from field service. But the reduction is not so great as might have been expected, had the great prevalence of the disease been entirely due to the supply of fresh susceptible subjects. And the statistical evidence shows that of late years men of the higher ages and of the longer periods of service have been attacked in higher proportion to their strength than formerly; which seems to mean that the virus of the disease is now more widely spread and virulent. With the resumption of the ordinary annual reliefs, this condition will probably go from bad to worse. Hence the protection of the individual men by inoculation would be valuable. Unfortunately the feeling with regard to that prophylactic is at present one of hope rather than of confidence. One hopeful measure which ought to be generally and thoroughly carried out is the routine disinfectant treatment, wherever it is possible, of all enteric fever patients from the beginning of the third week with urotropine, and the immediate redisinfection or destruction of the urine after it has been voided. It appears pretty clear that the water-supply as such is not always to blame, and equally clear that, even when the *supply* is pure, the virus must be frequently ingested in portions of water which have been casually contaminated after delivery, or which come from sources other than the pipe supply. And this local infectiveness which threatens the men through their water, is likely to be dangerous also through the food, and perhaps through the air.

Though it had no greater proportion of drafts than the others, the Bombay Command was the only one with a higher admission ratio than in 1899, due principally to the increase at Quetta, Poona, and Nasirabad.

There were 970 admissions and 289 deaths, against 1,392 and 348 in 1899. The average duration of a case was nearly 53 days; and the average number constantly sick 140·70, which being multiplied by 365 gives 51,355·50, the total annual loss of service from the disease.

Enteric Fever in the Geographical Groups.—Groups XIIa, VIII, V, and VI had, as usual, high decennial ratios of admission; and Groups II and X, and, to a less extent, I and IV, low ratios. In fact the coast groups seem to have least enteric fever. In 1900 all the groups except I were in ratio below their decennial average, the reduction being especially great in VI, XI, and V.

Enteric Fever in Stations.—Leaving out the small station of Taragarh, the highest ratios of 1900 were those of Nasirabad and Quetta. Certain points about these outbreaks have been mentioned above. There is a double, but insufficient, water-supply, exposed to contamination by flies and dust, at Nisirabad; and the men are apt to use the wrong supply because the boiled water takes long to cool. The highest decennial ratios were those of Sabathu, Cherat, Taragarh, Dagshai, Benares, Agra, and Lucknow; while low ratios were most common in Burma stations and stations near the sea.

Relation of Enteric Fever to Age and Length of Residence in India.—In 1900 the greatest liability to suffer and die from enteric fever was between the ages of 20 and 25 and in the first three years of Indian service. In 1899 the incidence of the disease had been less at all ages and in all periods of service than in the preceding year ; but in 1900 it was greater in all age periods except the second, and in all service periods except the first two. If the 24 years beginning with 1877 be divided into 4 periods of 6 years each, it will be found that for all the age periods from 20 to 40 the death ratios of the last are higher than those of its predecessors, and in some cases the increase is progressive through the lustra. Owing to a break in the system of record the results cannot be tabulated for periods of service in such detail, but, so far as they go, the results are similar.

Enteric Fever and Season.—In the decennium 1891-1900, so far as can be gathered from the non-calendar returns of the army, the maximum months for India as a whole were May, April, and August. But the maximum period differs in northern and in peninsular India. The bulk of the enteric fever at Quetta during six years has been from May, June, or July onwards to the end of November, 89 per cent. in the second half of the year ; while at Nasirabad admissions in the same period have been much more equally divided between the two halves of the year, 51 per cent. in the last six months. An attempt to connect this difference clearly with the meteorology has not been successful ; though it may be noted that the increase of mean temperature and the increase of range in the second-half of the year were proportionally higher in Quetta than in Ajmer (the nearest meteorological station to Nasirabad), while the increase of relative humidity and of rainfall were proportionally less. Quetta also exhibits a remarkable annual alternation of much and little enteric fever, the years of much enteric fever being 1896, 1898, and 1900 ; and 1901 appears likely to continue the alternation by being a year of comparatively little enteric fever. In contrast to this Nasirabad's enteric fever remained nearly constant from 1895 to 1898, but rose in 1899 and again in 1900. All endeavours, even with the kind help of the Meteorological Reporter, to connect these peculiarities with the available meteorological data have failed. Some attribute the outbreaks at Quetta to contaminated dust, others to contaminated water ; but the curious alternation just mentioned seems to indicate the existence also of some unknown factor. The wind records of Quetta have also been examined without result.

Plague.—In the European army of India there occurred 6 cases of plague with 1 death. There were 2 cases at Bangalore and Belgam, and 1 each at Aden and "on the march," the death happening at Aden. The man on the march contracted the infection in Belgam, and in all three stations the disease was present among natives. The man attacked at Aden was employed in the kitchen. At Bangalore one of the men attacked had up to the date of admission been keeping a native woman in one of the most infected streets in the Ulsoor district ; infection in the other case was supposed to have been contracted in some similar way ; and the medical officer considered it marvellous that more cases had not appeared, as the women the men went with were of a low dirty type, and lived in plague districts. No officers, women, or children were attacked.

Tubercle of the lungs.—There was a slight increase of morbidity and mortality from tubercle of the lungs. No remarks of general interest are made in the annual reports of the stations where most cases occurred. Flügge has recently published an important addendum to his previous work on the conveyance of tubercle infection through the medium of the air by means of cough-spray or sputum-dust. These experiments show clearly the great danger created by the patient and incurred by those in contact with him from ignorant or wilful carelessness, and justify the utmost hopefulness as to the adequacy of precise, scientific, yet simple, measures of prophylaxis.

Pneumonia and other respiratory diseases.—The admission rates and death rates from pneumonia were low as compared with the ratios of both the preceding year and the decennium. Indus Valley usually has the highest proportion ; but in 1900 Bengal-Orissa stood first, and this may be connected with the fact that Bengal-Orissa had more influenza than any other group, while Indus Valley returned none. January was the maximum month, and February came next. At Kurrachee the disease was attributed to a cold land wind in January, when the men were in camp.

Burma Coast had the highest ratio for other respiratory diseases, but Mhow, Rawalpindi, and Quetta were the stations which had most cases. Bronchitis was the most common of these affections.

Dysentery and diarrhœa.—Both the admission and the death ratios from dysentery rose, and medical officers of stations having many cases notice the severity of the type of the disease. Dysentery was, as usual, most prevalent in the Bengal-Orissa group ; but it was more prevalent in the Madras and Bombay Commands than in that of Bengal. The maximum month was August for India, Central India, and the Deccan, but not for Bengal-Orissa. By far the highest ratio was that of Barrackpore, where, the medical officer says, severe dysentery, very apt to be followed by liver abscess, prevails yearly. Something has been done to improve the drainage of Barrackpore, but it is reported that more requires to be done. Contaminated water from surface drainage is mentioned at Rangoon ; and at some stations damp, chill, and errors or carelessness as to food and drink are cited as contributory causes. In addition to these last, there is noticed at Neemuch the danger from the crowds of famine people wandering about.

In France Comte has lately emphasized the infectiousness of the disease, and attributed it to a coliform bacillus : while Lesage has isolated a balloon-shaped diplococcus from the blood, stools, sputum and organs of patient suffering or dead from dysentery. In a recent paper Flexner announces that he has had an opportunity of comparing in a thorough bacteriological manner the bacilli of Shiga, of Flexner, of Kruse, and of Strong, and has no doubt of their identity ;* "so that the justification for the view of a specific organism of dysentery would therefore appear to be near at hand."

The admission rate from diarrhœa was slightly increased, but the death rate much greater. High rates were those of Barrackpore ; of Neemuch, Nasirabad, and Mhow, in the famine tract ; and of Ranikhet. The second group had copious rain after drought ; and during the outbreak at Mhow the water contained more vegetable débris and suspended matter than usual, and the disease ceased by September, when the water had cleared a good deal. The epidemic at Ranikhet was of "hill diarrhœa," and was attributed to chills from the great fall of temperature on the onset of the rains.

Hepatic Abscess.—Both the admission and the death rates from abscess of the liver rose. The Bengal Command and the Burma Coast Group had the highest mortalities. There were 5 deaths each at Rangoon, Barrackpore, Lucknow, Mhow, and Poona ; and the highest death ratios were those of Barrackpore, Ahmedabad, and Saugor. Two of the fatal cases at Barrackpore, one with a single abscess and one with multiple abscesses, occurred immediately after attacks of influenza. At Rangoon one man just recovered from abscess of the liver associated with dysentery contracted enteric fever and died. A case at Jutogh was diagnosed by the help of the serum test as Malta fever, but on post-mortem examination the disease was changed to abscess of the liver.

As due to abscess of the liver were returned 95 deaths, but to these may be added 15 returned under other heads (enteric fever, dysentery, heatstroke, ague), in which examination of the body after death showed the presence of abscess of the liver. In these 110 the post-mortem record is complete only for 86, of which 46 were associated with ulceration, and 40 not associated. Out of the 40, 4 had scars of former ulceration, 2 had dysenteric symptoms without ulceration, and in 34 there was no trace, and no history, of either ulceration or dysentery.

Excluding 38 cases in which postmortem examination was omitted or was incomplete, the total number of fatal cases in which abscess of the liver was found in the 5-year period 1896-1900 was 453. In 238, or 53 per cent., there was found ulceration of the intestine, and in 215, or 47 per cent., no ulceration ; in 161, or 36 per cent., there was a single abscess, and in 292, or 64 per cent., there were more than one.

Among the 238 associated with ulceration, there was a single abscess in 66, or 28 per cent., while there were multiple abscesses in 172, or 72 per cent. On the other hand, when the suppurative hepatitis was unassociated with ulceration, there were 95 cases, or 44 per cent. in which the abscess was single and 120, or 56 per cent., in which the abscesses were multiple.

Again out of the total of 161 single abscesses, 66, or 41 per cent., were associated with ulceration, and 95, or 59 per cent., not so associated. In contrast to this, among the 292 cases of multiple abscess 172, or 59 per cent. were associated, 120, or 41 per cent., unassociated with intestinal ulceration.

It appears that a considerable proportion of cases of abscess of the liver are not connected with ulceration in the intestinal canal ; that the ulceration leading to liver abscess may be of any kind ; and that when there is no ulceration, there is a greater chance of the abscess being single than when there is ulceration.

---

*Shiga in D. M. W. XXVII, page 785, has since given a similar opinion.

Another case of multiple abscess from appendicitis has been recorded, also a case due to ascarides. A dysenteric abscess of the liver has been described in a child of 6 years of age ; and years ago in India a case was reported in which the child was only 6 months old, the cause unknown. Washbourn has noted that abscess of the liver is a rare complication of dysentery in South Africa, and Macfarlane that he has never seen a case in a native at Lagos, though dysentery is prevalent. Mott and Durham suggest that abscess does not supervene when the environment is normal ; but that there is something wanting in this explanation seems to be suggested by the frequency with which dysentery and abscess of the liver are said to be associated in Bosnia and Roumania.

The mortality from abscess of the liver in 1900 was 31 times greater among European than among native soldiers, while in 1899 it had been 32 times greater, and 25 times greater in 1898. On the other hand, the admission ratio from dysentery in 1900 among European soldiers was to the ratio of the native soldiers as 1 : 1·95, the difference being greater than in the four years preceding.

Venereal diseases.—The admission rate from venereal disease for India was 298·1, against 313·4 in the previous year, and 362·9 in 1898. In other words, in 1900 for every 1,000 men there were about 15 fewer admissions to hospital for venereal disease than in 1899. From the reports of medical officers it appears that the decrease was believed to be principally due to the absence of drafts of young men, to measures taken under the Cantonment Act for the expulsion or treatment of diseased women, to measures taken to warn the men, to keep them out of mischief, or to improve their cleanliness, and to the frequency with which bazaars, villages, localities, and areas were placed out of bounds on account of the prevalence of venereal disease, plague, cholera, or small-pox ; and that the ratio would have been still lower had it not been for the increase of solicitous prostitution caused by the famine. Other causes of the decrease of admission are mentioned, such as the continuous treatment of patients, which prevented relapses ; the out-patient system ; the prevalence of ague, which weakened the men and rendered them less inclined to venery ; confinement to cholera camps ; various measures adopted to remove temptation or lessen risk, such as : public lectures and private warnings with the object of increasing moral tone and self-control, and explaining the risks run ; the encouragement of temperance in drink ; warning the men against specially dangerous places, as on the march up to the hills ; encouraging games and athletics by day, and providing amusements and comforts in the evenings ; the provision of places and means of ablution ; encouraging the men to point out the women from whom, or the places where, they contracted disease ; laying down a rule that venereal patients after discharge from hospital had to make up the guards, &c., which had fallen upon others owing to their being in hospital. Various causes of local increase are given. In several cases putting the bazaar out of bounds was not productive of much or any benefit ; and at Poona the measure was followed by a great increase of clandestine and roadside prostitution. In fact, both in the plains and in the hills clandestine prostitution down the khuds and on the roadside was both more dangerous and more difficult to deal with than bazaar prostitution ; and prostitutes, when driven from one place, simply went to another beyond the limits of the commanding officer's authority, and let the soldiers know through touts. Soldiers often refuse to point out the women from whom, or the place where, they contracted disease ; and, of course, if the disease has been contracted in a locality out of bounds, they are only refusing to incriminate themselves. The amount of success attained in inducing the women to submit to treatment was very different in different stations ; and no doubt, personal influence counts for more than the mere taking of pains.

In 1900 there were 1,630·33 (against 1,851·31) men constantly sick in hospital from venereal disease. The average stay of a case of venereal disease is hospital was 32·97 days (against 31·89) ; and the total loss of service was about 595,070 days (against 675,728). There were 14 deaths (0·23 per 1,000 of strength), and 380 invalidings (6·28 per 1,000) directly due to venereal disease, against 14 or 0·21 per 1,000 of strength, and 442, or 6·53 per 1,000.

The only ratios over 600 per 1,000 of strength were those of Neemuch and Deesa. The greatest increases of ratio (increases of more than 100 per 1,000) were at Subathu. Gharial, Lower Topa (strength 59), Meiktila, Pallaveram (strength 81), Deesa, Neemuch, Nasirabad, Indore, Mhow, Satara, Mount Abu (strength 95), and Purandhur. The medical officers of Deesa, Neemuch, Nasirabad, Indore, Mhow, and Mount Abu refer to the large amount of disease caused by the numbers of famine-stricken women who resorted to prostitution to earn money enough to buy food.

Only the Bengal and Madras Commands shared in the decrease, there being a large increase in Bombay (influence of the famine), and a small increase in the Punjab.

Invaliding.—In the whole army of India 2,026 men were invalided, or 33·46 per 1,000 of strength, against 2,142 and 31·64 in the preceding year, the increase being greatly due to the larger number of men invalided for rheumatism and for debility, and being shared in by all the commands except Bengal. The proportion of invalids to strength was lowest in the Punjab and, as usual, highest in Madras. The percentage of men who were invalided while under 25 years of age to the whole number invalided was 52, against 59 in 1899. Of the total number of men invalided, 33 per cent. (against 38) were of less than two years' service, and 72 per cent. (against 81) were of less than five years' service. Invaliding from venereal diseases takes place pretty evenly through year by year of service and mostly at the ages of from 20 to 30. Invaliding from hepatitis, from debility, and from rheumatism is more affected by advance of age than by length of service, though the last service-period is that which sees the highest proportion of invaliding from these causes. For palpitation and valvular disease the greatest proportion of invaliding usually falls in the period between 20 and 25, though sometimes in that over 40, and in the first three or four years of service.

Officers.—The chief causes of admission among officers were ague and simple continued fever; and while the admission rates from cholera, small-pox, ague, and influenza rose, those from pneumonia, other respiratory diseases, enteric fever, dysentery, and hepatitic affections fell. The chief causes of death were enteric fever and cholera, but the ratio of the former was lower than in the previous year. Among the increased ratios were those of cholera, small-pox, and circulatory diseases. The admission rates from ague, tubercle of the lungs, respiratory diseases, hepatic abscess, and venereal diseases were lower than among the men, as were those of all the causes of death tabulated, except cholera and small-pox. One officer suffered from a second attack of enteric fever. Three cases were contracted in one hotel; two were attributed to impure milk; and two officers were supposed to have become infected when out shooting. One of the two stayed in a native village without filter or soda-water, and drank from any source when he was hot and thirsty.

Women.—The health of the women was not so good as in 1899. The chief causes of admission were debility, ague, and the diseases peculiar to women. All the diseases tabulated had higher admission rates, except pneumonia and dysentery. Debility caused about 38 per cent. of the total admissions, and ague about 18 per cent. Here it may be noted that at Subathu 21 of the cases of "debility" were due to childbirth; that at Rangoon 15 women were wrongly entered as debility simply to enable them to be with their sick children; and that at Meerut one death from debility and one from ague occurred in women recently delivered. The chief causes of death among women were enteric fever, dysentery, and cholera. All the diseases tabulated gave increased mortality, except pneumonia, hepatic abscess, childbirth, ague, and simple continued fever. Enteric fever caused nearly 14 per cent. of the total deaths. No special remarks of value are made by the medical officers as to the causation of the enteric fever of women and children.

Children.—There was a falling off in the health of the children. The chief causes of admission were ague, respiratory diseases, and measles. All the diseases tabulated gave increased admission rates, except whooping cough, measles, influenza, and enteric fever. Ague caused 22 per cent. of the total sickness, respiratory diseases 12½ per cent., and measles nearly 9 per cent. The chief causes of death were diarrhœa, debility, and respiratory diseases. There were increased death rates from all the diseases tabulated except convulsions, respiratory diseases, teething, simple continued fever, and cholera. Diarrhœa caused nearly 17 per cent. of the total deaths, debility (including immaturity at birth) over 12 per cent., and respiratory diseases over 10 per cent. Cases of measles were most numerous at Calcutta, Subathu, Rawalpindi, and Ferozepore. Three cases of scarlet fever occurred at Quetta, and one at Rawalpindi. The seven cases of diphtheria were divided between Fort William (two), Dum-dum, Sialkot (two), Peshawar, and Bangalore. At Sialkot it is stated that insanitary conditions likely to cause the disease were sought for but not found. There were 17 admissions from tubercle, the intestines or peritonæum being affected in five. The age of the only child that died of tubercle of the intestines (and lungs) was 16 months. No remarks are given about these cases. The liability to death was greatest under six months, the height of the percentage being, as usual, to a considerable degree due to cases of immaturity at birth. The liability gradually decreased up to 15 years of age.

Native Troops.

Sickness and mortality in 1900.—The health of the Native troops, like that of all other classes of the population, was worse than in the preceding year, as shown in the following table. The year was one of famine and bowel complaints, of malaria, cholera, and small-pox.

Year.	Average strength *	Ratio per 1,000 of Strength. Admissions into hospital.	Constantly sick.	Deaths from Cholera.	Remittent Fever.	Pneumonia.	Dysentery.	All causes.	Mortality, including absent deaths.
1896–1900 ...	127,223	781	30	1·03	1·14	3·36	·51	11·81	15·69
1899	128,529	795	38	·53	1·17	3·86	·35	10·70	14·50
1900	123,463	785	30	3·16	1·34	3·32	·63	14·04	18·57
1891–1900 ...	127,666	852	32	1·11	1·25	3·24	·59	12·22	16·62

* The quinquennial ratios are, of course, worked on the total strength of the lustrum.

The chief causes of admission were ague, dysentery, and venereal disease. Though there were lessened admission ratios from influenza and respiratory diseases, there were raised ratios from cholera, enteric fever, ague, dysentery, diarrhœa, small-pox, venereal diseases, scurvy, and tubercle of the lungs. Ague caused 41 per cent. of the total admissions. The chief causes of death were pneumonia, cholera, and remittent fever. Among the diseases which caused increased mortality, were cholera, diarrhœa, debility, dysentery, enteric fever, small-pox, malarial fevers, and tubercle of the lungs. Pneumonia caused nearly 24 per cent. of the total deaths, and cholera over 22 per cent. The total number invalided for discharge was 1,378, and the chief causes of invaliding were debility, rheumatism, and venereal diseases.

The small Mishmi Field Force suffered chiefly from ague and dysentery, and the China Expeditionary Force from ague, dysentery, and respiratory diseases.

If the following Table be compared with that on page 42, it will be seen that the native soldier suffered less from enteric fever, simple continued fever, diarrhœa, hepatic affections, and venereal diseases; equally from small-pox; and more from each of the other causes of admission given, than his European comrade. He also suffered more from scurvy. These relations are usual, except with regard to influenza, small-pox, and tubercle.

Ratios of Commands.

Commands.—Of the commands, Bombay was the most unhealthy, and it was also more unhealthy than in 1899. It had the highest mortalities from remittent fever, pneumonia, other respiratory diseases, dysentery, diarrhœa, and hepatic abscess. The highest mortality from enteric fever and from tubercle of the lungs was in Bengal, from cholera in the Punjab, and from small-pox in the Hyderabad Contingent.

Geographical Groups.—The most unhealthy group for the decennium was Assam; but for 1900, Bengal-Orissa. The change was not due so much to increase of disease in Bengal-Orissa as to improvement in Assam, an improvement of health shared in by the prisoners and by the general population. In 1900 Burma Inland had the lowest admission ratio from pneumonia, and the highest from other respiratory diseases; Bengal-Orissa the highest from ague and dysentery: Gangetic Plain the highest from influenza and enteric fever; Indus Valley the highest from cholera and pneumonia, and the lowest from venereal disease; Central India the highest from remittent fever, scurvy, and venereal disease; the Deccan the highest from small-pox; Western Coast the highest from

diarrhœa and hepatitis, and the lowest from ague; Southern India the highest from simple continued fever, and the lowest from dysentery and scurvy; the Hills the highest from tubercle of the lungs. In the decennium also pneumonia was most prevalent in Indus Valley and least so in Burma Inland, and remittent fever was least prevalent in Southern India.

* Excluding China Expeditionary Force, and including troops in Extra India not in the Indian Command.

Stations.—The highest death-rates of the large stations throughout India with a strength of not less than 1,000 were those of Kohat, Bombay, Edwardesabad, Secunderabad, and Abbottabad. In all these cholera broke out, very severely at Kohat, and severely at Secunderabad. They also all had high ratios from pneumonia, especially Edwardesabad. Bombay had in addition high ratios from diarrhœa, dysentery, ague, and plague; Edwardesabad from remittent fever; Secunderabad from beriberi and remittent fever; and Abbottabad from tubercle of the lungs and remittent fever. Besides the detachments of the 2nd Punjab Infantry on the frontier, which suffered principally from ague, the most unhealthy regiments were the Mewar Bhil Corps at Kherwara, the 19th Punjab Infantry at Sialkot and Kohat, the 2nd Bombay Grenadiers at Bombay, the 5th Punjab Infantry at Edwardesabad and Miranshah, and the Malwa Bhil Corps at Sirdarpore. The first two had outbreaks of cholera and much malarial fever; and at Kherwara there were in addition badness and dearness of supplies, with the result that the nutrition of the men was below par, and bowel complaints were common. At

Sirdarpore also the water was scanty and bad and the grain mouldy and fermented, causing dysentery and diarrhœa and guinea worm; and, besides, there was more malaria, and detachment duties were more frequent. The 5th Punjab Infantry had less influenza, malarial fever, and dysentery than in the previous year; but there was an epidemic of pneumonia.

Principal diseases: Influenza.—Influenza greatly decreased, the admissions and deaths being fewer than in any year since the disease invaded India in 1890. July and March were the maximum months in 1900; but for the eleven years' period April and March, with the minimum in October and September. The highest number of cases was 39 at Doranda in the Gangetic Plain. The native troops were far less affected than either the European troops or the prisoners. That prisoners are fonder of going to hospital than free men and that their being cooped up renders them more liable to pulmonary complication may explain their comparatively high ratios. A comparison of 1891–1900 with 1880–1889 does not reveal the expected increase of pneumonia, perhaps because, in accordance with the Nomenclature, influenzal pneumonia is returned as influenza, and not as pneumonia.

Cholera.—There were 666 cases (641 admissions) of cholera with 390 deaths, against 126 with 68 in the preceding year; and the admission and death-rates were, of course, much increased, and also much above the decennial rates. Cholera reached its maximum in July; but it was present every month, especially May-September. By far the most important outbreak was that at Kohat in which the 19th and 6th Punjab Infantry, and the 3rd Punjab Cavalry, specially participated; and the next highest numbers were at Secunderabad and Kherwara. A special investigation into the Kohat outbreak was made by Major Firth, who agreed with the local medical officers that it was directly attributable to specific pollution of the irrigation water which runs freely through Kohat. Though he was unable to satisfy himself of the existence of Koch's spirillum in the irrigation water, the ready detection of spirillar and allied forms was considered sufficiently confirmative of the suspicion attaching to the stream. The 19th Punjab Infantry, which was the regiment most severely affected, arrived, free from cholera, in Kohat on the morning of the 6th July. Either from a misconception as to the propinquity of the pipe supply, or from ignorance of the danger from the irrigation water, the men, under the stress of marching in on a July morning, consumed large quantities of the irrigation water. During the next 48 hours 26 cases of cholera occurred among the sepoys and followers, and on the next day 61 more. Removal of the corps to a camp away from all irrigation and to a water above suspicion rapidly checked the outbreak. It is not known how the irrigation water became infected, but the disease was at the time spreading epidemically in the Punjab, and the first reported death in Kohat city occurred on the 5th July. The men of the 6th Punjab Infantry and other regiments are also supposed to have drunk the polluted irrigation water, because it was so much cooler than the pipe water. At Secunderabad the disease had become epidemic in the city and neighbourhood before it appeared in the regiments. The 24th and 11th Madras Infantry suffered most. With regard to the Kherwara cholera in the Mewar Bhil Corps, it is stated that it was probably caused by a polluted water-supply, and ceased when some wells sunk in the old river bed were closed.

Small-pox.—There were 78 cases of small-pox with 4 deaths, against 46 with 2 in the preceding year, and the admission ratio was above the decennial. The cases were mostly mild, in vaccinated men. Thus, Secunderabad with 21 cases had only 1 death. No other station had more than 4 cases. The 11th Madras Infantry had 10 cases, and no other regiment more than 4. The infection was derived from the general population, in which there was a recrudescence of the disease.

Ague, remittent fever, simple continued fever.—To ague was due nearly 41 per cent. of the sickness of the native army. The year being wetter than its predecesor, an increase of ague was to be expected, and the increase was, of course, not confined to the native troops. The most malarious group was Bengal-Orissa, but it was less malarious than in 1899. The greatest increase was in Group VIII., which comprises many of the districts where plentiful rain succeeded famine-drought, and the next greatest in Group VI., wherein is included much of that part of the Punjab in which conditions were somewhat similar. The most malarious month was October, and the least malarious March. The highest number of cases was in the 5th Bombay Infantry, its first year at Aden; the 28th Punjab Infantry at Wana; the 12th Bengal Infantry at Alipore, but

fewer than in the previous year; the 8th Bombay Infantry at Delhi, newly arrived from Ahmednagar at a time when malaria was rife at Delhi; the 1st Bengal Infantry in Mauritius; and the 13th Bombay Infantry at Deesa in Group VIII. The medical officer of the 1st Bengal Infantry mentions there were fewer cases in the regiment owing to its being stationed on a healthy plateau in the interior of the island, where he was only able to find one specimen of *anopheles* in the course of the year; and that most of the admissions took place early in the year, while the men were still feeling the influence of the malarious climate of Port Louis, where *anopheles* is plentiful.

Remittent fever caused 9½ per cent. of the total deaths; and prevailed most in October and least in February, though it was pretty evenly distributed throughout the months of the year. The death-rate was high, the admission rate rather low. It was most prevalent in Groups VIII, XII, I, and VII. The greatest numbers of cases were at Kohat, Rawalpindi, Kila Drosh, Edwardesabad, Peshawar, Maymyo, and Agra; and hill stations garrisoned by Gurkhas had high numbers, which is suggestive in view of the fact that Gurkhas suffer much from tuberculosis as well as comparatively much from enteric fever. The 10th Madras Infantry at Maymyo, and the 4th Bengal Infantry at Agra (from Calcutta) had the highest numbers; and next came regiments at Kohat, Almora, Sirdarpore, Abbottabad and Kohat, and Peshawar.

That the reports of medical officers are not uniformly favourable is, in the light of present knowledge, a call to more method and perseverance in the prophylactic use of quinine in sufficient doses.

The 4th Infantry, Hyderabad Contingent, at Ellichpur, and the 26th Madras Infantry at Vizianagram, had the most cases of simple continued fever: and in the latter they are said to have been due to exposure to the sun at musketry and to fatigue duties in building the new barracks. In the 16th Madras Infantry at Singapore the cases were afterwards thought to have really been influenza. Exposure and chill were the causes assigned in the 3rd Madras Lancers at Secunderabad.

Enteric fever.—There was a great increase both in the admission and in the death rate from enteric fever. The ratios for European troops are very unlike those for native troops and prisoners; and, as the total death ratio for fevers (ague, remittent, simple continued, enteric) among European troops was to that among native troops as 2·5 : 1, the difference cannot have been altogether due to want of recognition of the disease among the latter. As usual, the ratios of the Gurkha regiments taken together were higher than those of the native troops as a whole.

The results obtained by Major Freyer in the testing of the blood reaction of natives were criticized in the report for 1896, page 71, and have been finally disposed of as erroneous in a recent paper by Captain Lamb. In the same paper by the narration of 11 cases it is shown that enteric fever among natives of India is commoner than is sometimes supposed, and that the serum test is a trustworthy means of recognizing it, the diagnosis in two of the cases being supported by the results of *post-mortem* examination. Major Burke has lately stated that the disease, though rare in ordinary natives of India, has been seen by him many times among Parsis and among members of the native aristocracy, the former having no caste, and the latter being often above caste prejudices. But it is noteworthy that, though 4 of the patients reported on by Lamb were native Christians and 1 a Goanese, 3 were Brahmins and 3 Hindus, and therefore not likely to be Europeanized in food or other habits. According to what has been already said, it seems possible that the increase in cases returned among natives may not be altogether due to the improved methods of diagnosis now available, but in part also to a greater prevalence and intensity of the infective material. If this be so, the increase should continue. Evidence as to the frequent occurrence of the disease among the Chinese goes on accumulating, one of the most interesting recent contributions being that of Clark, which offers anatomical as well as clinical proof.

In the whole native army of India 54 cases with 18 deaths were returned, as against 18 with 3 in 1899. Abbottabad, Benares, and Dehra Dun had the highest numbers of cases. To the total 16 regiments contributed, but the 42nd Gurkhas no less than 29 admissions, mostly at Benares and on the march. Neither in the case of this regiment nor in that of any other do the annual reports throw any light on the origin and causation of the disease. In some cases the serum reaction test was used in diagnosis. In only two of the fatal cases was a *post-mortem* examination obtained, but in both the result was quite confirmatory of the clinical diagnosis.

There were returned 7 cases of Malta fever, 2 from the 23rd Pioneers at Meean Meer, 2 from the 29th Punjab Infantry at Peshawar, 1 from the 7th Bengal Mountain Battery at Datta Khel, and 2 from the Malakand Force. The diagnosis in the cases of the last

two corps was clinched by the sedimentation test with the *Micrococcus Melitensis*. In addition, Lieutenant Greig of the Malakand Force tested the blood of 15 men who had been in hospital with prolonged "remittent fever," and with that of one, several months after his discharge from hospital, obtained a positive reaction.

Plague.—In 1900 there were 56 cases (55 admissions) of plague with 29 deaths, against 76 with 45 in 1899, and 94 with 58 in 1898. The comparative immunity of the sepoys as compared with the populations surrounding them is ascribed to the large number of men inoculated, many of them twice, and to the immediate segregation of patients and evacuation of buildings whenever cases did occur. The 15th and 21st Madras Infantry at Belgam, where plague was raging, had between them 31 cases and 13 deaths, and the case which occurred at Vizianagram was imported from Belgam. Four corps at Bagalore had only 12 admissions and 4 deaths among them. All the five cases in the 27th Madras Infantry in Mauritius were fatal; but the disease was checked by removal to the uplands. Four cases at Bombay, one at Poona, one at Alipore (imported from Fulta), and one on the march at Ratlam, make up the total.

It has been suggested that the failure of limejuice in certain cases may be due to an obscure gradual decomposition, and that the limejuice used should always be as fresh as is obtainable.

Tubercle of the lungs.—There was a rise in the admission and death rates from tubercle of the lungs, the rise of the former being greatest in Bengal and of the latter in Madras. The Bengal Command had the highest admission and death rates, and the highest group admission ratio was that of the Hills; these relations being connected with the fact that the Gurkhas suffer more than other native soldiers from pulmonary tuberculosis. The five highest numbers of cases were in Gurkha regiments. The highest number of cases was in the 1–2nd Gurkha Rifles at Dehra Dun, but no reason is given. The medical officer of the 1–4th Gurkha Rifles at Bakloh blames insanitary barracks and the overcrowding of the married quarters, and the medical officer of the 43rd Gurkha Rifles at Shillong says that the remarkable and sudden increase is attributable to the overcrowding associated with small cubic and superficial space per man in the barracks. In the 1–1st Gurkha Rifles at Dharmsala the liability of his men is connected by the medical officer with their "fatal habit" of alternating woollen and cotton clothing regardless of the time of day or of the season of the year. Nothing is said as to any racial liability of Gurkhas; and if their higher ratios are simply due to bad sanitation, it is high time that something was done to prevent waste of life among these valuable soldiers. The space per man should be made ample, and never encroached upon; and European methods should be adopted to secure ventilation at times when the doors and windows are closed on account of cold.

As non-tubercular phthisis were returned 25 cases with 6 deaths. Because it is not likely that all these cases were really non-tubercular, it is to be hoped that fewer will be so returned in future.

Pneumonia and other respiratory diseases.—Coincident with, and perhaps partly dependent on, the decrease of influenza, there was a fall in the admission and death rates from pneumonia. In 1900 pneumonia caused 24 per cent. of the total mortality, and was, as usual, the chief cause of death. Admission was, as usual, highest in Groups VII and XII, and mortality in Group VII; but Western Coast and Central India had both higher mortality than the Hills. Both in Group VII and in Group XII pneumonia was most prevalent in the cold months, especially in January; and the same was the case for India as a whole. Among the stations with the highest ratios were Sibi, Miranshah, Edwardesabad, Mir Ali Khel, Kohat, and Naini Tal. The regiments which had most cases were the 5th Punjab Infantry at Edwardesabad and Miranshah, the 11th Bengal Infantry at Miranshah, the 6th Punjab Infantry at Kohat, the 2nd Sikh Infantry at Datta Khel, the 8th Bengal Infantry at Lucknow and Naini Tal, and the 4th Punjab Infantry at Kohat. In the 5th Punjab Infantry the disease was epidemic for about two weeks, and then suddenly subsided, though there were a few dropping cases afterwards. Malarial debility from former residence at Wana was considered to have rendered the men unduly susceptible. In the 11th Bengal Infantry the disease is described as having been epidemic malignant, septicæmic, and infectious; and the sick-attendants were not allowed to stay in the hospital longer than 48 hours. In the 2nd Sikhs the disease was ascribed to cold winds and chill; and in the 8th Bengal Infantry to malaria, chill, and dust, and not in any case to infection. The 3rd Punjab Cavalry at Kohat had only 8 cases, and the medical officer says that the disease was "non-infectious

this year," and due to malaria with chill. He adds that pneumonia patients must always have plenty of ventilation and cubic space, and that the sick attendants must be frequently relieved and never allowed to sleep in the ward. The carrying out of these rules may have been the reason why his cases were non-infectious and therefore few. At any rate, and especially if preceded by early diagnosis, they are sound preventives of spread.

Evidence as to the infectiousness of pneumonia is not confined to India, and there seems some reason to believe that when the disease is about, the nasal secretion as well as the sputum may be infectious. Pneumonia is, of course, only one of the pathological results which may be achieved by the pneumococcus. The period of incubation appears to be very short.

Other respiratory diseases were most prevalent in the Bombay Command, in the Burma Inland and Assam groups, in the stations of Mir Ali Khel, Wana, and Fort Sandeman, and in the 23rd Bombay Infantry at Mir Ali Khel and Fort Sandeman, the 6th Punjab Infantry at Kohat, and the 8th Bengal Infantry at Lucknow and Naini Tal. The causation is referred to chills, especially at the beginning of the cold weather and in malarious subjects.

Dysentery and Diarrhœa.—The admission and death rates from dysentery in 1900 were high. The greatest increase and the highest ratio were in Group IV. Of the 25 stations of over 100 strength which had ratios over 100 per 1,000, 11 were on the north-west frontier, five in the famine districts of Group VIII, three in Bengal, two in Ceylon, and one each in Groups III, X, V, and VI. Among those stations the highest admission ratios were those of Jandola, Kajuri Kach, Sarwekai, Tank (with Jatta and Draband), and Dibrugarh; and the highest death ratios those of Kherwara and Kajuri Kach. The 27th Punjab Infantry, and the 12th, 23rd, and 7th Bombay Infantry, all on the north-west frontier, the 13th Bombay Infantry at Deesa, and the 9th Madras Infantry at Colombo, had the highest numbers of cases. In the 12th Bombay Infantry the causes assigned are cheap fruit and polluted river water full of silt; in the 7th Bombay Infantry the cold of the climate after Jubbulpore; and in the 9th Madras Infantry change of diet and climate. Dysentery prevailed more in the second half of the year than in the first, the maximum month being October.

The diarrhœa ratios were considerably increased, and the greatest prevalence was in Western Coast. The 2nd Bombay Infantry, as in the previous year, had by far the largest number of cases, which the medical officer attributes to insufficient warm clothing in the wet cold months. The next largest number was in the Mewar Bhil Corps at Kherwara in the famine area, and the causes assigned are the poor quality of the food and the deficient water supply.

Venereal Diseases.—While among European troops an average strength of 60,553 gave 18,049 admissions, in the case of native troops an average strength of 123,463 gave only 5,242 admissions. In other words, there were only 42 admissions for every 1,000 men among native troops, against 298 for every 1,000 among British troops.

The admission rate was 8·4 per 1,000 of strength more than in 1899. There were nine deaths and 129 invalidings, directly due to venereal disease. The Bombay Command and the Hyderabad Contingent had the highest ratios and the greatest increases, and only Madras had a lower ratio. In all the commands the ratios of native troops were much lower than those of European troops. In 25 stations (against 20) the admission rate from secondary syphilis was over 20 per 1,000 of strength, and in 46 it was over 10 per 1,000. In India the ratio of primary syphilis *plus* soft chancre rose by 4·3 per mille of strength, that of secondary syphilis by 0·5, and that of gonorrhœa by 3·6. The Bombay Command and the Hyderabad Contingent had the highest ratios for primary syphilis *plus* soft chancre and for gonorrhœa, and the Bombay Command and the stations outside the Indian Command the highest for secondary syphilis.

As usual, the Gurkhas suffered much. The high ratios of the Gurkhas and of the troops stationed in Ceylon illustrate the well-known fact, referred to in the reports for 1895 and 1896, that men in a strange land, and perhaps separated from their families, are more prone to contract venereal disease. The Gurkhas also take no trouble to save themselves by cleanliness. Various minor reasons are given for the prevalence of venereal disease in different stations. But by far the most important increase of disease was in certain stations and regiments of the Bombay Command and the Hyderabad Contingent; and in the case of at least a dozen regiments, stationed at Erinpura, Deesa, Ahmedabad, Sirdarpore, Ajmere, Mhow, Sehore, Aurangabad, and Hingoli, the medical officers

attribute this to the extension of prostitution caused by the famine. This cause of increase, as has been already mentioned, was also potent in the case of European soldiers.

Beri-beri.—All the 146 cases of beri-beri (against 202) occurred in Madras regiments, 95 in the peninsular part of the command, 42 in Burma, and nine in the Bengal Command. The regiments which had most cases were the 11th Madras Infantry at Secunderabad, the 8th Madras Infantry at Rangoon and Port Blair, the 9th Madras Infantry at Bellary, Colombo, and Trincomalee, and the 26th Madras Infantry at Vizianagram. In the first it attacked natives of the East coast, who are considered to be very subject to the disease, and was most prevalent when the men were exposed to cold and wet in cholera camp. In the second the disease was almost entirely confined to the Hindu sepoys, at least in the case of the detachment at Fort Blair. The rest of the free population and also the prisoners were quite free from the disease, and no explanation could be found in dietary, &c. In the third there was improvement after resort to the issue of 4 oz. of meat daily. The medical officer of the fourth considered locally grown rice to have something to do with the causation, and issued bread instead.

Other evidence besides the above has been brought forward as to difference in racial liability. Fresh circumstances have also been recorded which tend to emphasize the part which articles of food are supposed to take in the spread of the disease. A new hypothesis is that *Blatta orientalis* serves as an intermediary between the man already infected and the man to be infected. Captain Rost believes that he has discovered the microbe agent of the disease in an angular bacillus found on rice; and the claim of a new coccus has been put forward by another observer. Some attention has been drawn to the possibility that cases of chronic arsenical poisoning might be wrongly diagnosed as beri-beri.

Jails of India.

Sickness and Mortality in 1900.—The year 1900 was hot and rather dry, with an approximately normal rainfall. But actual famine here, and the effects of famine there, were still present; and cholera, small-pox, and some other epidemic diseases were active; so that the health of the prisoners, like that of the general population was bad. Many of the prisons also were overcrowded.

The chief causes of admission to hospital were ague, dysentery, abscess, and diarrhœa. Among the diseases with raised admission rates were cholera, small-pox, influenza, dysentery, ague, and tubercle of the lungs. Ague caused 37 per cent. of the total sickness, and bowel complaints 18 per cent. The chief causes of death were dysentery, pneumonia, and tubercle of the lungs. Among the diseases with increased mortality were cholera, small-pox, gangrene, malarial fevers, pneumonia, and bowel complaints. Dysentery and diarrhœa caused 28 per cent. of the total deaths, pneumonia 13 per cent., and tubercle of the lungs 12 per cent.

A somewhat serious feature of the year was the increase and spread of cerebrospinal fever.

Administrations.—The prisoners of Assam, the Andamans, and the North-Western Provinces alone had better health than in the previous year; and the difference was considerable only in the case of Assam. The three most unhealthy administrations were, in order, the Andamans, Berar and the Central Provinces; and the three most healthy, in order, Madras, Burma, and the North-Western Provinces and Oudh. Of the former group, the Andaman and Berar had ratios higher than those of the quinquennium. As compared both with the previous year and with the quinquennium, the year 1900 had increase of mortality in the Andamans from remittent fever, pneumonia, diarrhœa, and debility; in Berar from cholera, respiratory diseases, bowel complaints, and tubercle; and in the Central Provinces from cholera, small-pox, remittent fever, tubercle and debility. Of all the administrations, the Andamans had the highest death rates from remittent fever and tubercle of the lungs; Berar from pneumonia, other respiratory diseases, dysentery, and diarrhœa; and the Central Provinces from cholera, small-pox, and debility.

* The quinquennial ratios are, of course, worked on the total strength of the lustrum.
† Excluding subsidiary jails.
‡ Including Ajmere, Quetta, and Mercara.

Andamans.—The rainfall was somewhat below that of the previous year, and much below the lustral average. Sickness and mortality showed a slight improvement. Increase of malarial fevers began with the advent of the south-west winds and rain in May; but

many of the cases treated were relapses in old cases from exposure. Quinine and cinchonidine were issued as prophylactics during the rainy season. An epidemic of influenza began in April, and another in November. The presence of a certain amount of scurvy, beyond what was returned, is attributed to the absence of good fresh vegetables and the rather monotonous diet of the prisoners. The list of vegetables given by the Senior Medical Officer is certainly not satisfactory, and it is to be hoped that the measures mentioned in the report for 1898 are being continued and pushed. Boiled water is provided at all the stations where many labouring convicts reside; but it is stated that cases of acute diarrhœa, often fatal, are caused by prisoners quenching their thirst at wayside sources. Efforts should be made to ensure that labouring prisoners always have ready access to the boiled water. After the invalid gang, the new arrivals had, as usual, the highest proportional mortality. The settlement has generally been distinguished by high death rates from remittent fever, tubercle of the lungs, and dysentery. Now, if the death rates of the ten years period before the report of Mr. C. J. Lyall and Dr. Lethbridge, 1882-1890, be compared with those of the ten years 1892-1900, the result is—

——	Remittent Fever.	Tubercle of the Lungs.	Dysentery.	All Causes.
1882-1890	2·97	4·28	4·16	27·33
1892-1900	4·11	4·29	10·08	33·89

The worst years in the second period were 1892, after the cyclone of November 1891, and 1899, a year of drought. Taking the above given rates of the first period as the standards, then remittent fever and all causes had high mortality in all the years of the second period, except 1896, 1897, and 1898; tubercle of the lungs in the years 1897, 1898, 1899, and 1900; dysentery in all the years. Separate accommodation has been provided for tuberculous patients, and reforms have been carried out in the water and vegetable supplies, &c., but the above statistics show how much remains to be done.

Burma.—The prisoners in Burma were fairly healthy. The Prome jail was overcrowded throughout the year, but was not unhealthy, perhaps because the population was kept in movement by monthly transfers. The overcrowding in eleven other jails was transient. The well water of some of the jails contained from 70 to 100 grains per gallon of total solids, but no ill effects were observed. The system of conservancy by trenching in the jail gardens is not found to be a cause of ill health in the jail population. The increase of tubercle was chiefly in the Central jails of Insein and Mandalay; and it is noted that the cases were segregated "as much as possible," and that care was taken to detect them at an early stage. The chief outbreak of cholera was at Bassein. Its origin was not traced, but food and flies were suspected to have been carriers of the infection. The medical officer of the Moulmein jail says that nothing short of removal of the jail to a higher and dryer site will effect permanent impovement, especially with regard to tubercle and dysentery.

Assam.—The health of the prisoners of Assam was most unusually good, and the population of the province was "fairly healthy." The chief feature was the great reduction in cholera, diarrhœa, and non-pneumonic respiratory diseases. There was also less malarial fever, and prophylactics were administered with apparently good effect. Improved accommodation is believed to have lowered the mortality in the Sylhet jail. The Tezpur jail, which recorded increased sickness and mortality, was situated amid a population extensively affected by bowel disease. As to the effect of the partial stoppage of extramural labour during the year by order of the Chief Commissioner, the Inspector-General considers it too early to judge.

Bengal.—The health of the Bengal population was bad, and so was that of the prisoners. Some jails were overcrowded as the result of disturbances and scarcity among the people. The statement that "even when there is no actual overcrowding, if the numbers are kept up continuously to the limit of the capacity, there is a marked increase in the number of cases of pneumonia and phthisis," seems to indicate that the officially sanctioned allowance of floor and cubic space is not sufficient. Excluding subsidiary

jails, there were 169 cases of cholera, of which 87 ended fatally, distributed over 21 jails; the most severe outbreaks being those of Palamau, Alipore, Chapra, and Champarun. At Alipore the disease appeared suddenly in the jail, and coincidently in various parts of Calcutta, after a heavy shower of rain. Prisoners from a cholera district were supposed to have brought the infection into the Palamau jail; and, indeed, it is stated that in nearly all cases the introduction of cholera was traced to newly admitted prisoners, to prisoners attending court, or to contaminated water outside the jail. Cerebrospinal fever and plague also occurred, as will be noticed below; and there was an increase of mortality from remittent fever (though malarial fever was less frequent), tubercle of the lungs (attributed to the increased crowding in jails), pneumonia, other respiratory diseases, dysentery, diarrhœa, and debility. There is reason to believe that some of the attacks of bowel disease were dependent upon the presence of intestinal parasites; and pneumonia appeared in the Ranchi jail in an epidemic form at the time when it was overcrowded with prisoners, owing to disturbances among the people. The Inspector-General notes that the seven Pasteur-Chamberland filters installed in Bengal jails have not proved very successful, while they are very costly and liable to get out of order.

North-Western Provinces and Oudh.—The North-Western Provinces and Oudh were "healthy, though not free from epidemic disease," and the health of the prisoners was fairly good, cholera, small-pox, and debility being the only diseases in the table with increased mortality. In the districts of Jhansi, Orai, and Lalitpur many of the men admitted into jail were suffering from the effects of famine. Every endeavour was made by transfers to prevent overcrowding of particular jails. The Inspector-General favours the reduction of the height of inner dividing walls, and an increase of the vegetable ration. There were no great outbreaks of cholera, but cerebrospinal fever appeared in three jails. The substitution of a new jail for the old one has been successful in reducing the once notorious mortality at Gorakhpur. The use of quinine prophylactically is only mentioned with regard to one jail.

Punjab.—The standard of health of the prisoners admitted to the Punjab jails in 1900 was low, on account of the prevalence in the province of famine, fevers, and bowel affections. The jails had increased mortality from cholera, small-pox, tubercle of the lungs, pneumonia, dysentery, and debility. There was a high mortality from sunstroke, owing to the late appearance of the monsoon rains. A great increase in the jail population made it necessary to accommodate large numbers of prisoners in tents in different jails; and tubercle of the lungs increased. The Inspector-General is taking measures to secure the construction of a special tubercle ward for the segregation of phthisical patients. The prisoners did not suffer so much as the general population from malaria, owing to their being placed in better sanitary conditions, and being defended by prophylactic doses of quinine. Cholera prevailed to a serious extent only at Mung Rasul. The outbreak was attributed to the drinking of water from an infected village well by prisoners working on canal excavation. At Ludhiana a virulent form of dysentery disappeared after the prisoners had been supplied for some time with fresh potatoes and onions. The Inspector-General believes that under the circumstances of the year mortality from pneumonia would have been higher had it not been for the attention paid to ventilation and cleanliness.

Bombay.—Famine and disease were prevalent in the Bombay Presidency, and the health of the prisoners was bad. The jail population was much increased, and all the jails, except three, were overcrowded throughout the year, so that relief could not be afforded by transfer. There was increased mortality from cholera, small-pox, remittent fever, tubercle of the lungs, pneumonia, dysentery, diarrhœa, and debility; and cholera, relapsing fever, and plague occurred in certain jails. The most serious outbreaks of cholera were at Thana and Dhulia. In both cases cholera was prevalent outside the jail. In the former the origin of the disease in the jail was not traced, and 19 buildings out of 21 furnished cases. In the latter the first case occurred in a man who drank water from a contaminated *nala* that flowed through the jail garden. It is not stated how such a *nala* was allowed to run open within the jail enclosure. Malaria was also prevalent, and cinchona alkaloids were issued prophylactically where necessary. Other measures adopted to improve the health of the prisoners were the issue of wheat instead of inferior cereals, the issue of potatoes instead of inferior vegetables, the issue of extra diet, special diet, extra clothing to weakly prisoners. The insanitary moat which surrounded the Thana prison has at length been filled up.

Berar.—Berar also was afflicted with famine and disease, and the prisoners admitted to jail were below par. The prison population was greatly augmented, and mortality from cholera and bowel complaints, from tubercle of the lungs, pneumonia, and other respiratory affections was much increased. But the heavy mortality was confined to Amraoti, Akola, and Basim. At Amraoti there was an epidemic of severe influenza, frequently ending in fatal pneumonia, an outbreak of cholera, and, during the rains, a food grain which was believed to be deficient in nutritive value. This last was brought to notice by the medical officer, and the necessary change was at once made. The difference between the high mortality in these three jails and the low mortality at Ellichpur, Buldana, Yeotmahl, and Secunderabad is not fully explained.

Central Provinces.—Famine and disease were rife in the Central Provinces, and though special executive orders prevented the swamping of the accommodation by hordes of physically deteriorated prisoners, yet all the jails, except two, were overcrowded at some time. Relief was obtained by utilizing worksheds inside the jails as sleeping barracks, and by extramural camps, the latter being, on the whole, a great success. It is noted that the physical condition of men admitted to jail was on the whole better than in the famine of 1897. There was increased mortality under all the heads given in the table; and cerebrospinal fever also occurred, especially at Raipur. In eleven jails there were 64 cases of cholera and 44 deaths, the highest numbers being at Nagpur, Nimar, Sambalpur, and Seoni. It is stated that the disease at Seoni was traced to impure milk, the boiling having been neglected. For the difficulty mentioned by the Inspector-General as to different systems causing variations in the number constantly sick a solution was provided in paragraphs 7 and 8 of Chapter VII. of the report of the jail commission of 1889, and sanctioned by the resolutions of the Government of India founded thereon.

Madras.—Scarcity and disease in the Madras province increased the number of prisoners, and made their physical condition bad. The general death-rate, though higher than in the previous year, was less than the lustral ratio. The increase was greatest in the district jails, and least in the central prisons. There was increased mortality from all the diseases shown in the table, except non-pneumonic respiratory diseases and debility; but only the ratios for remittent fever, tubercle of the lungs, diarrhœa, and debility were above their quinquennial ratios. Privation had affected many of the men admitted into the Cannanore and Vizagapatam jails; there was dysentery at Russellkonda, thought to have been caused by the effect of drought upon the water-supply; and Nellore and Russellkonda were the jails which suffered most from cholera. It was not discovered how the disease, which was prevailing in the town, got into the jail, especially as the persons and clothes of all newcomers were washed and disinfected; though it was thought that perhaps the warders might have been instrumental. The first man attacked had been 13 days in jail, and came from a locality where there was no cholera. Into the Russellkonda jail it is said to have been imported from a cholera area. Quinine was issued prophylactically with fair regularity in five jails, the reports from three being favourable. The Parvatipur jail was closed, as it was found the hillmen could be kept in good health at Vizagapatam.

Coorg. Rajputana. Baluchistan.—The Mercara jail was more healthy than in the previous year, the Ajmer jail much more unhealthy, and the Quetta jail slightly more unhealthy. The Ajmer jail was overcrowded, and the prisoners admitted were suffering from the effects of the prevailing scarcity.

General Population.

General Remarks.—Those whose duty or interest in the subject has led them to a perusal of this section in previous years will be acquainted with the difficulties that confront the vital statistician when dealing with the figures presented in the annual reports of the provincial Sanitary Commissioners.

In view of the recent orders of the Government of India to bring the remarks on this subject within a briefer compass, it is not considered desirable to restate these difficulties, and to those unacquainted with the conditions a reference to the report for 1899 is recommended. But it may be said that as regards the year's results now to be reviewed the prospect of arriving at exact conclusions must necessarily be more remote from the fact that the census figures of 1891 are still the basis of calculation of the birth and death rates and of the quinquennial averages, and that the calamitous famine, which directly affected four large provinces and, indirectly, others, has profoundly altered the population figures both in actual numbers and in distribution.

And in addition to famine, pestilence in the form of cholera and epidemic fevers which prevailed to an extent without a parallel in previous records, has introduced another vitiating factor into the account of inestimable force. Beyond the extra loss of life thus involved over and above what may be deemed due to "natural causes," the effect of these visitations in setting up tides of immigration and emigration would suffice to impair the validity of the best accredited registration returns. But we know that, as regards the effect of cholera, the returns are defective, and although many of the deaths so caused have doubtless been reported under other heads, it cannot be doubted that a considerable number have escaped all record. If to these considerations be added the fact that at present nothing is certainly known of the alteration in the distribution of the population due to the more permanent and normal inducements to change domicile which have operated during the decade, it will be admitted that close reasoning based on the recorded ratios is a task beset with fallacies.

The census of 1901.—The final enumeration of the census of India was made on March 1st, and the provincial totals were published just two weeks later, a remarkable feat due to the adoption of a new system and to the perfection of the arrangements made by Mr. Risley, C.I.E., the Census Commissioner; unfortunately the provincial sanitary reports are compiled for the most part during the first quarter of the year, and the new figures will not be taken into general use until 1902. It has subsequently transpired that the corrected totals vary from those first announced to an altogether infinitesimal degree, and the broad results may be stated, while at the same time no attempt will be made in this report to discuss their significance in detail, a task that must be reserved till after the publication of the final and full results by the Census Commissioner.

So far it is known that the population of all India, British and Native territory, has risen in the decade from 287,317,048 to 294,266,701 giving an increase of only 2·42 per cent., which, however, on account of the inclusion in the gross total for 1901 of the population of several outlying tracts* never before enumerated, gives an unduly favourable result; comparing the areas actually enumerated in both census years, the increase in the latter amounts to only 4,283,069, a rate of 1·49 per cent., as compared with an actual rate of increase of 11·2 per cent. in the previous decade.

But this result is again considerably modified if we differentiate between British territory and Native States; in the latter the aggregate population has fallen off by nearly 3 millions, *i.e.*, by 4·34 per cent. on the population of 1891, which stood at 66,050,479, while the actual increase of nearly 10 millions in the former, from 221,266,569 to 231,085,132, is at the rate of 4·44 per cent.

The figures for the different Native States are terribly significant of the effects of famine, which were not alleviated, to anything like the same extent as was found possible in British territory, by organized measures of relief; for this we must look partly to the smaller financial resources of these States, to the greater extent to which they suffered, as a rule, from the failure of the monsoons and to the lower standard of living and the less resistant powers of the aboriginal tribes. Baroda shows a decrease of 19 per cent.; the Bombay States one of 14 per cent.; Rajputana and the Central India States suffered

* Shan States and Chin Hills: Sikkim; Kurram Valley; Baluchistan Agency; Bhil tracts and Rajputana; Nicobar and Andaman islands.

losses of 18 and 17 per cent. respectively, figures which are far greater than those afforded by any of the British provinces, the details for which are given in the accompanying statement :—

Province.	Census variation per cent. 1881-91, + or —.	Population as shown by the census. 1891.	1901.	Census variation per cent. 1891-1901, + or —.	Natural increase or decrease as shown by excess of recorded births over deaths, or vice versa. Total Births 1891-1900.	Total Deaths 1891-1900.	Difference.	Percentage natural increase or decrease, + or —.

Here again we cannot avoid the conclusion that famine and prolonged scarcity have played a chief part in producing the extraordinary variations in the actual increases and decreases, though subsidiary factors have doubtless been in operation. The first two areas on the list have certainly been free from famine and plague, but both have the advantage of a considerable and constant influx of immigrants. Madras has suffered from scarcity (in 1896-97 and again in 1899-1900), plague, though not widely epidemic, has figured in the returns of 10 districts, and it has lost by emigration to an extent not at present known.

In the Punjab famine was prevalent in some 10 districts in 1899, which returned to these and extended throughout three other districts in 1900, when scarcity was elsewhere generally felt; plague may be said to have been endemic in at least two districts since 1897, while cholera prevailed widely in 1892 and 1900.

In Bengal, while actual famine has not declared itself, widespread scarcity and high prices have been a feature of its economic history during three of the ten years; plague has claimed a larger number of victims than the records take account of, and cholera is reported to have been the cause of about 1,300,000 deaths in five of the ten years in question, a number nearly equal to the death-roll of the previous decade from this one cause. In the North-Western Provinces famine, which had prevailed in Bundelkhund in 1896, extended over a much larger area in 1897, while to cholera 542,000 deaths were ascribed in the three years 1891, 1892, and 1894, a number which is little short of the total for the whole of the previous decade from this cause. As to the Bombay Presidency, Berar, and the Central Provinces, the history of the first has been writ large in the public journals; plague has been endemic for five years, famine and scarcity have been superadded, and in five of the ten years cholera has been exceptionally prevalent. In Berar the year 1897 was one in which the people stood upon the verge of famine, and in 1900 famine was at its worst throughout the year; in four of the ten years cholera was abnormally severe. Lastly, in the Central Provinces the people have passed through two of the severest famines on record, from the autumn of 1896, throughout 1897, and in 1900; five of the ten years were also marked by exceptionally heavy cholera epidemics.

It is certainly not desirable, nor is it desired, to minimise the significance of the facts disclosed by the recent census; the above sketch of the untoward conditions against which

the people have had to struggle, if it affords a knowledge of the proximate causes, serves at the same time to direct attention to the economic conditions and sanitary shortcomings under which existence is passed by masses of our fellow-subjects, and which a failure in the supply of the natural fertilizing agent of the soil and of the prime necessity of life—water—brings out with such lamentable emphasis. For the facts set forth are susceptible of only one interpretation as regards the proximate cause of a situation that is receiving the earnest attention of the Government of India. Those parts of India, British or Native, which are adequately watered naturally or artificially, and which escaped famine, show an advance, modified doubtless in parts from their physical and economic relations to the rest; while those where rain is under ordinary circumstances capricious and scanty, and where in the last half of the decade it may be said to have failed, and where there are no systematic irrigation works, we have the famine areas with consequent mortality, emigration, and impaired fecundity, all inducing a decline in population.

Allusion has been made to the capricious as well as to the scanty character of the rainfall, to which many parts of the country are frequently subject. And truly it may be said that the results of an ill-distributed and superabundant precipitation are on the whole more disastrous than even drought: they are certainly more dramatic and ultimately more tragic and exhausting. The effects of floods and of the consequent epidemic fevers are writ large in the statistical annals of the year and of the decade, and, if the truth could be demonstrated, it would be evident that the people have suffered more severely, directly and indirectly, on this account than from famine and its results. Beyond the immediate prostration by fever of practically the whole population in areas subjected to floods, so that agricultural operations are suspended, and whole tracts thrown out of cultivation, there is the terrible mortality and the long persistent debilitation of the survivors which has a far more marked effect in impairing fecundity, and so of delaying restoration, than famine. One example of this state of affairs is cited later in this section, but these facts must be borne in mind in endeavouring to appraise the causes that have led to some of the remarkable results disclosed by the census.

If we take the nine provincial areas under registration in British India (excluding Burma) we find a net increase during the last decade of 7,641,893; had the natural increase followed in the same proportion as in 1881–1891, the number would have risen to 20,271,548; that is to say, there are over 12½ millions, distributed thus: Bombay, 3 millions; Madras, 3 millions; Central Provinces, 2 millions; North-western Provinces and Oudh, 2 millions; Bengal, 1½ millions; Punjab, ⅔ million; Berar, ⅓ million,—less than under ordinary conditions might have been expected. But it is altogether fallacious to take this figure as the measure of the direct loss due to excess mortality. Account must be taken of the effect of migration and of the lessened fecundity, due to famine and scarcity, on the birth-rate, that is to say, we have to distinguish between loss from excess mortality and a diminished source of supply. A reference to the birth statistics of the affected areas will show how far short of the normal expectation recruitment fell during the last half of the decade, with the notable exception of the year 1899, having due regard to the natural increase in the population since 1891. But neither the actual numbers nor the millesimal rates represent the truth in any year; the births registered may roughly be said to fall short of the true number by from one-third to one-fifth in different provincial areas, and the difficulties in arriving at any reliable estimate of the loss caused by a lowered birth-rate are very great. But a study of the available data, read in the light of this knowledge, would appear to indicate that under the stress of famine and pestilence there were at least some five millions fewer children born than might have been expected under ordinary conditions, this figure being arrived at provisionally and pending the further light which the Census Commissioner will doubtless throw upon the subject. In endeavouring to arrive at an estimate of the true loss from this source, account must be taken of the mortality which this number of infants, if born, would have suffered, which may be put at from one-third to two-fifths of the whole in the first year of life.

While we repeat that no one can study these results without grave concern, it must be admitted that the outlook has some redeeming aspects. Newspaper critics, whose conscientious sympathy one may well respect, have pointed to the actual and the might-have-been as indicated by the last two census returns, and have deduced a wholesale loss to the population without alluding to any modifying factor or its source and without discriminating as to its results. It has been shown that the estimated loss is, to a large extent, not to be attributed to excess mortality, and it may be added that the period of enforced celibacy and physiological rest will have its reaction on the return of normal conditions; fecundity will be increased, and in this sense a considerable part of the "loss" is in the nature of a deferred interest or increment which will later appear in the

account. The birth-rate may be expected to rise by one-fourth or one-fifth on the normal in the year following restoration, and to a smaller extent in the subsequent year, and this will probably mean an addition of some three millions to the population in British territory only, and beyond the normal increase (see section V. of Annual Report for 1899, pages 103–106). Beyond this, regrettable as the loss by excessive mortality has been, it is not a theoretical assumption that this has fallen to the largest extent on the unfit, the diseased, the unproductive, on those who consume at the expense of the productive, and who are a burden of more than the proverbial feather's weight when the balance between income and expenditure is so narrow. The facts furnished by the history of the Central Provinces, which are given in some detail under the provincial sub-section, may be considered in support of this assertion. If, as we may perhaps reasonably hope, the cycle of deficient and ill-distributed rainfall has worked itself out and a cycle of normal conditions is to to set in, we may at least congratulate ourselves that we enter the new decade with a population much better equipped for the ordinary struggle of existence, more resistant, and with a disproportionate number in the reproductive age periods, which will by being less subject to mortality further tend to ensure a balance of increase.

Indeed, the considerations of gravest concern to which a study of the vital statistics and of the habits of the people give rise are, perhaps, those which are at present inherent in the normal conditions, and especially one would point to the high infantile mortality rate which accompanies prosperity and to the undoubted fact that though the large majority of the people are at a great disadvantage in the struggle on account of deficient nourishment on which powers of "resistance" so largely depend, yet it may be asserted that the physiological value of the food ration they usually obtain is ample to sustain that measure of health which depends on a sufficient supply of nourishment. The explanation of this paradox lies in the nature of the food to some extent, but more largely on its methods of preparation from the stage of the raw grain to the stage when it is considered fit for consumption in the universal form of unleavened cakes. The grain is, as a general rule, dirty and very imperfectly ground and sifted, and cooking is but half consummated, so that much of the food is literally consumed raw with adventitious indigestible material; defective mastication is also a common and serious factor in the sum of the causes that go to produce the economic loss, which in the aggregate is enormous, especially when the proportion of unassimilated proteid in vegetable food is considered. Any one who has conducted sewage purification experiments in this country will confirm these views; it is not only that the average weight of the daily solid excreta is on the average quite $2\frac{1}{2}$ times that of the European on a mixed and well-cooked diet, but that in the excreta are incorporated a quantity of raw or semi-digested food materials. This is not only so much food value lost, but, as shown by the habitual double daily evacuation, the energetic peristalsis set up is inimical to the full assimilation of the rest. The art of cooking receives very little attention, and, indeed, has developed, among the masses, little beyond the stage of primæval man, and when the food consists almost entirely of grain and pulses this defect is the more serious, for adequate cooking goes far towards producing the results which it is the function of the digestive organs to complete. It is therefore not difficult to understand why bowel complaints occupy such a prominent place in the true causes of mortality and why the natural resistance to all forms of disease is wanting. It is in this direction, as well as in the reform of marriage customs, in the diffusion of knowledge as to the care of infants, and in the awakening of the spirit of enterprise that will lead the surplus population of congested areas to seek fresh and freer fields elsewhere, that "civilization" in its best sense has so large a part to play for the welfare of the people of India. These are reforms that can only come from within, but while the fundamental functions of self-preservation and propagation are either so misunderstood or so misapplied, the vital statistics will always bear the stamp of a lamentable waste of lives.

As regards the effects on the records of mortality, of famine and pestilence during the year under review, the reader is referred to the admirably careful and lucid discussion of the subject presented in the Report of the Famine Commission of 1901. In a final summary the total number of deaths recorded in the five actual famine areas (British) during the year 1900 is compared with the decennial average number and a balance of excess to the extent of about $1\frac{1}{4}$ million deaths is exhibited against the year under review. But, as has been pointed out, the number was inflated to a large but unknown extent by the deaths of immigrants from Native States, who came across the borders in a deplorable state—often in a dying state. The impression left by the evidence was that one million excess deaths occurred among British subjects, and that at least one-fifth of this mortality was due to cholera alone.

Referring to the census table on page 70, it will be noticed that the "variation per cent." based on the registration returns of births and deaths, is in some cases very similar to the actual variation per cent. as disclosed by the census; in other cases there is a strong contrast. It need only be said here that no reliable indication of the correctness or defectiveness of registration is afforded by this comparison. This important question is about to be examined critically on receipt of the full and final Census Report, which, among other data, will furnish estimates of the gains and losses in each province by migration, and the general results will be set forth in the Annual Report for 1901. Apart from the disturbing effect of migration, it may merely be noted that even where registration is notoriously defective a variation based on the records may approximate closely to that disclosed by the census if the registration of the births and deaths is proportionately defective. If the recorded average birth-rate is 30 per 1,000 against a true rate of 45, and if the recorded death-rate per 1,000 is 22 against a true rate of 37, it is obvious that the "natural increase" is the same in both cases. To mention only one case, viz., that of the Madras Presidency, the variation by natural increase based on the records is 7·2 per cent., and the census variation is identical, yet there is abundant evidence to show that registration is defective, if not to the precise extent, yet in the nature of the example just quoted. The whole subject is beset with difficulties, which arise partly from the great variations in the effectiveness of registration in different areas, and no one modifying factor applying generally, and partly from the extraordinary variations exhibited by the recorded "actuals," which are truly "tropical" in their ebb and flow under stress of the changing conditions of life. No better evidence of this can be desired than the figures recorded in most provinces during the last three or four years, and some striking examples are quoted in a subsequent part of this section. Taking the Central Provinces during the last five years we get the following birth and death rates :—

—	Birth-rate.	Death-rate.	Natural increase or decrease.
1896	31·72	49·31	−17·5
1897	26·83	69·34	−42·5
1898	29·91	24·30	+ 5·6
1899	47·35	28·09	+19·2
1900	31·90	56·75	−24·8

Nothing could testify more eloquently to the vicissitudes under which the people have lived and died, while at the same time the actuary and the vital statistician may well find themselves at a loss before the uneven tenour of these figures.

Before leaving the subject of the preliminary results of the recent census, allusion may be made to a feature of great sanitary interest disclosed by the figures returned for a large area in the Western Doab (the Ganges-Jumna Mesopotamia) of the North-Western Provinces. The area comprises some eight districts where canal irrigation is systematically carried out, with the consequence that up to the early part of the last decade water-logging of the soil was a general feature of the country. Not only had the fertility of the soil deteriorated by the efflorescence of "reh" in many parts, but the prevalence of fatal forms of fever laid a heavy tax on the life of the population, and when the census of 1891 was taken it was found that in the four northerly districts the population had only advanced by 3·4 per cent. on the figures of 1881, against an average of 6·34 for the whole province, and this in spite of a never-failing series of good harvests. But the four southern districts, which had also suffered from floods and the epidemic fevers consequent thereon, actually showed a decrease of 4·3 per cent., and in the early "nineties" the revenue assessments in many villages had to be revised and reduced owing to the depopulation and the poverty induced by disease and by the deterioration of the soil. Since then drainage operations on a very extensive scale have been undertaken, many hundreds of miles of drainage "cuts" having been made, and beyond this, the alignment of many of the irrigation channels having been redressed. The results of this

beneficent policy are apparent in the new census figures; the percentage increase of population in the first four districts is no less than 14·4 per cent., and in the lower four districts 12·2 per cent., the most astounding contrast with the previous census results being furnished by Etah, perhaps the most severely affected in the former period. At the census of 1891 the percentage *decrease* for the decade was given as 7·25, while at the recent census the population of this district was shown to have increased to the extent of 23·09; doubtless emigration in the former period and immigration in the latter played a considerable part in the results. As has been observed, one can scarcely doubt that the cost of the drainage cuts and of the remodelling of the canal-channels will be more than repaid by the increase of assessment which the increased cultivation in this area will probably admit of in the revenue settlements now in progress. The people of this area have enjoyed complete immunity from anything approaching scarcity in contrast to the lot of their fellows in other parts of the province and in the Punjab, and indeed they have reaped a rich harvest in ministering to the necessities of the latter from the ample stock of suplus food grains at their disposal. The object lesson is one of great importance and of far wider application.

The following statement furnishes a brief epitome of the Birth and Death Statistics recorded in 1899 and 1900 :—

Birth and Death Statistics.

Province.		Total number of births registered.	Ratio of births per 1,000 of population.	Mean ratio of births per 1,000 during previous five years.	Number of deaths registered.			Ratio of deaths per 1,000 of population.			Mean death-rate during previous 5 years.			Number of deaths of males to every 100 deaths of females.

* Excluding Europeans and Eurasians. † Excluding Zamindaries of the Chhattisgarh Division.

Bengal.—In 1899 the total number of births registered in Bengal was 3,053,178, the highest on record, yielding a ratio per 1,000 of 42·96; in 1900 the actual number fell to 2,749,582, which is 38·68 on the old census population, and 36·95 on the figures just announced (1901), while the mean of the previous quinquennium is 37·66, which is, of course, not corrected for the increase in population; the birth-rate may therefore, be

described as fully up to the average of recent years. A falling-off in the number of births of 303,596 as compared with the total of the previous year, large as it may seem, loses its significance when the circumstances are considered; the high birth-rate of 1899 was due to a return of prosperity and plenty after a period of scarcity and wandering in search of work. During the later months of 1899 the tide again turned; scarcity and high prices began to prevail and extended through the year under review, and this, together with the excessive prevalence of epidemic disease, makes it a subject of congratulation that the birth-rate was, at any rate, fairly maintained at the recorded normal. This, then, was the outstanding feature of the general provincial birth-rate, and it will serve no useful purpose to contrast more closely the phenomena in different areas in the two years. The birth-rates in districts (including towns and rural areas) ranged from 49·19 per 1,000 in Noakhali, and 46·83 in Tippera, to 28·53 in Hooghly and 15·8 in Calcutta; in towns, we have, at one end of the scale, rates of 62·63 in Garulia and 56·23 in Joynagar, and at the other end 5·07 in Jhalakati and 4·94 in Nawabganj, all situated in or near the area of the 24-Parganas, and all subject to great fluctuations of population which make the recorded ratios fallacious.

As regards rural areas, Sherpur (Mymensingh) is credited with a rate of 57·66, and Chandpur (Tippera) with one of 54·86, while Nawabganj gives 20·49 and Serampore 16·93, and these last again are both in the Presidency area where as a general rule the sex-distribution and a floating population militate against high birth-rates, a subject that has frequently been discussed in these reports.

Throughout the province as a whole 105 males were born to every 100 females, but this proportion was subject to large variations in different areas.

The total number of deaths registered in 1900 was 2,603,736, which is 34·99 per 1,000 on the census population of 1901, but amounts to 36·63 on the old census figure (in either case the highest on record), against 31·21 in the preceding year and 30·12, the decennial mean (1890–99). While therefore in 1899 the births exceeded the deaths by 834,935, the "natural increase" in 1900 was only 145,846, a deficit of not far short of three quarters of a million. As we have seen, the birth-rate was extraordinarily high in 1899, and about the average in 1900, and, consequently, it is the rise in the mortality in the latter year which at once claims attention. Now, as regards mortality the year 1899 was about the average, but there were 385,493 more deaths recorded in 1900, an increase of about 5·4 per 1,000 on the last census population. The increase per 1,000 in the districts, excluding towns, amounts to 5·17, while in the towns (containing about 5 per cent. of the whole population) it rose to 10·3 per 1,000. The following statement exhibits the factors of this increase:—

—	Districts.	Towns.
Cholera	3·37	2·89
Small-pox	·08	·64
Fevers	1·28	2·91
Dysentery and Diarrhœa	·30	·93
All other causes	·19	3·02
	5·2	10·3

The cholera mortality is dealt with in a subsequent section of this report; 345,878 deaths were recorded from this disease, giving a ratio per 1,000 of 4·86, against 1·51 in 1899, and 2·5 the mean of the decennium.

To "fevers" are ascribed no less than 1,703,804 deaths, equal to 66 per cent. of the total mortality; this number yields a death-rate of 22·9 per 1,000 on the last census, the decennial mean (1890-99) being 21·8. In this respect, again, the year stands out as one of exceptional unhealthiness, the districts of Dinajpur, Jalpaiguri, Faridpur and Malda having as usual an unenviable pre-eminence, with death-rates ranging from 36 to 40 per 1,000 from this cause alone. The physical causes to which this high mortality is attributed, in the brief but graphic accounts furnished by the local medical officers, leave little room for doubt that true malarial fevers are a predominant factor in these

deplorable results; we read of the silting-up of rivers and the consequent stagnation of drainage water; of floods due to abnormally distributed rainfall; of large tracts of country becoming stagnant marshes in the monsoon period; and, for the rest, bad drinking-water from surface sources, and overcrowded ill-ventilated dwellings.

As might be expected with cholera everywhere epidemic, the same causes were in operation to raise the death-rate from dysentery and diarrhœa. To these diseases 64,664 deaths were attributed (0·86 per 1,000 on the recent census), whereas the mean for the decennium is only 47,304. As usual the urban rate was more than five times that of the rural, a result largely due to more exact diagnosis in the towns, and which suggests grave doubts as to the correctness of the returns, as regards the prevalence of bowel complaints, among the great mass of the population.

One of the striking features of the statistics of the last three years is the extraordinary rise on the mortality under "all other causes." In 1898 the total returned was 320,081; in 1899 it rose to 413,301, and for the year under review it is 436,568. The increase is more notable in urban than in rural areas, and must be considered too large and too sudden to be altogether referable to improved diagnosis. It is significant that this great rise has been synchronous with the prevalence of plague, and that about 40 per cent. of all this excess mortality since 1898 was returned from one division, Patna, where plague has been endemic. It is well known that deaths from plague are often ascribed by the people to any and every other cause, to stave off preventive measures, and when the medical history of the year is summed up, the conclusion can scarcely be avoided that plague, which is dealt with in a subsequent section of this report, has been second only to cholera as a cause of the extraordinary transformation that the vital statistics have undergone.

As regards the death-rates reported for the different sects, Muhammadans and Hindus suffered at the rate of 38·36 and 36·48 per 1,000, respectively; Christians follow with 27·06, then Buddhists with 26·58, while Other classes, for whom the returns are least reliable, died at the rate of only 23·36 per 1,000.

Assam.—The year 1900 was one in which the number of births recorded was considerably above, and the number of deaths considerably less than, the decennial average, which was however raised by the enormous mortality of 1897; if this year be excluded, the number of deaths in 1900 is quite up to the average. There is however some justification for congratulation on "a fairly healthy year," if only on the ground that it was one of the three in the decade in which the births exceeded the deaths. If the total number of deaths registered in Assam during the 10 years 1891–1900 is set against the total number of births, a natural decrease of 126,915 or 2·5 per cent. is exhibited. The new census however shows an actual increase of 688,533 or 12·67 per cent. To what extent this increase is due to immigration cannot be estimated until the Census Report is available, but the province has not suffered from famine or scarcity and is, indeed, considered to be free from the risk of such a calamity, and the contrast exhibited above must, to a considerable extent, be attributed to defective registration of births, of which the returns exhibit abundant evidence. The alternative conclusion is that the natural conditions of life in Assam are so bad as to rapidly lead to depopulation by excessive mortality, which is not warranted by the evidence available. This question will be dealt with in a survey of the results of registration of vital statistics in the different provinces based on the disclosures of the recent census which will be instituted by order of Government when the full census report is available.

The total number of births recorded was 184,427, a ratio of 34·96 per 1,000 on the recent census figure; in the previous year the actual number was 176,770, or 35·5 per 1,000 on the uncorrected population, the mean of the quinquennium being only 30·63. When the figures for the two great valley areas, into which the province is naturally divided, are examined a notable difference is disclosed; the Surma Valley yielded a birth-rate of 39·14 and a mean of 33·07 for the previous 5 years, while the Brahmaputra Valley returned a rate of only 30·73, which is only about 2 per 1,000 above the quinquennial average. This great contrast is largely due to imperfect registration in the latter area, though doubtless epidemic disease has been more prevalent, and the general standard of health and of living are lower, in the Brahmaputra Valley. The question of registration is however one to which the Government of India have directed the serious attention of the local authorities with a view to the reconsideration of the employment, for this purpose, of unpaid village headmen, or if this agency be found

indispensable, to the adoption of more stringent control and check of their work. In this respect there appears to be room for great improvement, as a study of the returns furnished by the Police and the Vaccination Staff abundantly proves.

The total number of deaths rose from 154,326 in 1899 (ratio 31·0 per 1,000 on the old census figure) to 161,631 or 30·64 on the population enumerated in 1901, the mean of the previous 5 years being 35·44 per 1,000. While the quinquennial averages recorded for the two valleys are 36·08 for the Surma and 34·80 for the Brahmaputra, the death-rate in the former in the year under review was 29·9 against 31·39 for the latter. The districts of Nowgong and Darrang in the latter area stand out from the rest with rates of 53·03 and 44·09 respectively, and this is due to the prevalence of cholera and fevers in epidemic form. The history of the former disease is detailed in a subsequent section of this report, but it may be noted here that 60 per cent. of the total mortality from this cause in the valley occurred in these two districts ; 24·95 per 1,000 of the population were reported to have succumbed to this disease in Nowgong and 9·6 per 1,000 in Darrang.

To "fevers" 77,557 deaths altogether were ascribed, giving a death-rate of 14·7 per 1,000 of population against a quinquennial average of 20·13, and this includes 9,036 deaths from "Kala-Azar," which recent research has shown to be probably a malignant form of malarial fever. The disease was first recognized in Nowgong in 1891, and during the last seven years no less than 65,590 deaths have been ascribed to it in this district ; it subsequently spread to Darrang, Kamrup, and Goalpara, all in the same valley, and it has recently made its appearance in Sylhet in the other valley. It is satisfactory to be able to report that the mortality which averaged annually 16,138 in the four districts named for the five years ending 1899, fell in 1900 to 9,012, of which about one-half were reported from Nowgong alone.

The average death-rate in districts was 30·64 per 1,000, for towns 38·62, and for rural areas 30·48, and a comparison of these figures affords further evidence of the defectiveness of registration among the bulk of the population. The towns in Assam are comparatively small, nineteen having an aggregate population of only 102,574, and the conditions cannot be greatly dissimilar to those prevailing in the rural areas with which they are associated. Taking the mean rates for the last 3 years the following contrast emerges :—

——	Cholera.	Small-pox.	Fevers.	Dysentery and Diarrhœa.	Other causes.	All causes.
Rural	1·7	0·5	15·1	2·4	7·5	27·5
Urban	3·0	0·3	18·1	6·0	9·8	37·8

The excess of 10 per 1,000 in the towns, amounting to over 36 per cent. on the rural rate, is significant, if not convincing, of the failure to secure full reports of vital phenomena in the villages.

For the different sects the death-rates were as follows :—Other classes, 54·67 ; Muhammadans, 30·71 ; Hindus, 26·76 ; and Christians, 25·64.

North-Western Provinces and Oudh.—The number of births registered in 1900 was 1,892,169, against 2,255,627 in 1899, the millesimal ratios being 40·34 and 48·09 respectively, calculated on the uncorrected census figure of 1891 ; on the new census the rate amounts to 39·7, and the quinquennial mean is 37·37, so that all that can be said is that while the extraordinary fecundity displayed in the previous year (due to the circumstances fully described in the last report) has not been maintained, the birth-rate is well above the average. In 25 districts the rate is above, and in 23 below, the average for the province, and once again, the Western Doab area, where irrigation is very generally in operation, holds pride of place. The only noticeable features of what is described as a healthy year are the very low rural death-rates in the Kumaon (26·4), Lucknow (27·4), Allahabad (28·0), and Gorakhpur Divisions (24·6), and, with this, the comparative rise in the birth-rates generally in the eastern and central areas of the province, where, as a rule, they are notably lower than in the western area.

The deaths numbered altogether 1,460,139 against 1,556,821 in 1899, giving ratios of 31·13 and 33·19 respectively, against a quinquennial mean of 32·7. On the new census figure the rate for 1900 is 30·6.

The Sanitary Commissioner remarks that "there is no great departure from the average to call for any special comment beyond the fact that the year was a healthy one, although not free from epidemic disease." It must however be pointed out that the urban mortality was exceptionally high. The quinquennial mean for all towns having a population of 10,000 and upwards is 39·16, but in 1900 it rose to 42·13, while the rural rate for the whole province was only 30·31. Forty-eight of the 99 towns return death-rates above the quinquennial (urban) mean, eighteen have rates of over 50 per 1,000, and in 24 more the rates are between 40 and 50. That nearly 50 per cent. of all the municipal towns should record this high mortality, while doubtless indicating effective registration, is also suggestive of specially untoward conditions to which the urban population is subject, especially when the year is pronounced to have been "healthy."

Cholera, which is dealt with in a subsequent section of this report, is reported to have caused 84,960 deaths (1·81 per 1,000), the most considerable outbreak occurring in the Sultanpur district, where there were 17,174 deaths, equal to a rate of 15·96 per 1,000 of population.

To fevers 1,106,030 deaths were attributed (23·58) against 1,245,260 (26·55) in the previous year, the quinquennial mean ratio being 25·89. The districts most severely affected were those situated in the canal irrigation areas and those bordering on the notorious Tarai. Much has been done to secure the adequate drainage of the former, with a result which has been noticed in the prologue to this section (see page 73), but it is almost inevitable that the inhabitants of irrigation districts should pay for their abundant crops by a somewhat greater incidence of malarial fever.

The mortality from dysentery and diarrhœa was slightly higher, and that from "all other causes" notably less, than in the previous year, and, as regards the former, considerably less than the quinquennial average.

The death-rate among Muhammadans was 30·89 against 31·55 in 1899; among Hindus, 31·22 against 33·52; among Christians, 13·79 against 11·62; while among Other classes it was 22·61 against 18·36 in the previous year.

Punjab.—If we compare the births and deaths registered in the Punjab in the last two years, the following striking result is shown:—

—	Births.	Deaths.	Increase or decrease.
1899	994,001	607,725	= + 386,276
1900	843,970	980,211	= — 136,241

Now the average annual number of births registered for the decade was 844,643, and of deaths 705,902, so that the births in 1900 were up to the average, while the deaths were in excess by 274,310. While this leaves out of account the increase due to a larger population, it focusses fairly the main features of the vital statistics for the year, viz., an average birth-rate, and an excessive death-rate.

The births give a ratio of 37·76 per 1,000 on the new census, and one of 41·1 on the population of 1891, and this is 7·3 below the rate returned in 1899, a year of exceptional fecundity, and even at the reduced figure the Punjab maintains its foremost position in this respect. As compared with the previous year there was a notable falling-off in twelve districts, and this is justly attributed to severe famine in some, to scarcity in others, and to general movement of population from most of these. On the other hand, in no less than 14 districts out of the 31, the birth-rate was actually above the quinquennial mean.

In spite of a considerable disproportion between the sexes in the Punjab, and in spite of notoriously defective registration in the frontier districts, the provincial rate is always exceptionally high in comparison with that of other provinces; the ratio for the past decade calculated on the population of 1891 works out at just over 41 per 1,000, and if the calculation be made on double the female population, it rises to 44·3 per 1,000. This is doubtless partly due to efficient registration over the Cis-Indus area, and for the rest we must look to factors of race, to marriage customs and environment, including food. In the famine-affected areas the birth-rate fell off in different districts to the extent of from 8 to 20 per 1,000, but the population was so affected by emigration that it is impossible to make any exact deductions of the actual effect of the calamity in this respect, and the returns for next year must be awaited.

The total number of deaths recorded was 980,211, or 372,486 more than in 1899, and 274,309 above the decennial average. The ratio per 1,000 on the new census figure is 43·9 and 47·7 on the population of 1891, against 29·6 in 1899 and a quinquennial mean of 30·5. In 12 out of the 31 districts there was an excess of deaths over births ; Hissar heads the list with an excess of 71·8 per 1,000, then follow Ferozepore with 44·0, Rohtak with 35·2, Karnal with 33·9, Umballa with 24·5, Ludhiana with 15, Lahore with 12·6, Gurgaon with 11·6, Delhi with 10·4 and Montgomery with 7·8. These were the districts most severely affected by famine and scarcity and, to some extent, as a consequence, by epidemic disease, cholera and fevers, to which three causes the excessive mortality is attributed, and which gave rise to a death-rate of 96·4 in Hissar, 86·8 in Ferozepore, 73·7 in Karnal, 68·0 in Rohtak, 61·5 in Umballa, 60·4 in Ludhiana and 59·4 in Lahore district.

The average death-rate recorded in the towns was 54·55 against 46·92 in the rural circles. Some of the towns situated in the famine areas suffered very severely, but much has to be attributed to the confluence of refugees to relief works. Kaithal in Karnal (population 15,768) had a death-rate of 161·59, chiefly due to epidemic "fever" and to cholera ; Zira (Ferozepore) with only 4,356 inhabitants returned a rate of 160·47, of which fever accounted for 134·3 per 1,000 ; and Sirsa (Hissar) with a population of 16,415 lost 2,571, giving a ratio per 1,000 of 156·63, of which fever and cholera claimed the great majority. On the other hand, in the frontier districts many towns had a rate of less than 20 per 1,000.

The facts as regards the mortality from cholera are given in the subsequent section ; there were in all 28,260 deaths recorded from this cause (1·37 per 1,000), and considerably more than half the total were registered in five of the districts most severely stricken by famine.

Small-pox was just twice as prevalent as in the previous year, and here again the famine districts suffered most heavily along with Peshawar, where the disease is endemic.

The mortality ascribed to fevers accounted for 685,895 deaths or 70 per cent. of all recorded ; this number gives a ratio per 1,000 of 33·37 against 19·54 for the quinquennial mean. In Hissar and Forozepore the mortality amounted to 70 and 69 per 1,000 of the population respectively, and in Karnal and Rohtak it was over 50 per 1,000. All these districts were famine stricken, and the fatal form of the disease burst out with epidemic virulence in September "in consequence," it is said, "of floods due to excessive rainfall." In August the number of deaths recorded was 39,060, in September it rose to 66,351, and in the following months of October and November the appalling figures of 129,170 and 125,410 were registered. No details of any researches into the special pathology of the disease are recorded, but is believed to have been a malignant form of malarial fever acting on a population enfeebled by privation.

Dysentery and diarrhœa, as was to be expected, were more fatal than usual, and the increase over the average mortality was fairly general throughout the province, though it fell with special force upon the famine stricken areas.

It only remains in this brief review to give the incidence of mortality on the different sects. Hindus died at the rate of 52·83 per 1,000 against 30·7 in 1899 ; for Muhammadans it was 43·62 against 28·55 in the previous year ; for Native Christians 32·16 against 18·23 ; while for Other classes the enormous rate of 170·6 was recorded against 138·45 in 1899, but it is noted that the classification under this head is erroneous, and it may be added that there were only 6,067 persons included therein at the census of 1891.

Central Provinces.—The number of births registered during the year was 303,121, a decrease of 146,774 on the total of 1899, when, however, the highest number ever attained was recorded. The ratio per 1,000 of the population of the recent census was 30·8 and on the old census 31·9, against 47·35 in the previous year and a quinquennial mean of 33·98. The falling off then is not so great as might be expected in a year described as "one of dire famine and distress." In 1897 when famine was also widely prevalent "but in a less severe form," the number of births fell to 254,973, or 26·83 per 1,000, but it must be remembered that this rate was greatly influenced by distress and scarcity and even famine in the latter half of 1896.

All districts share in the decrease when the figures are contrasted with those of 1899, and in all save two the rate was below the decennial mean, and in all save five the number of deaths exceeded that of the births ; all over the province the "natural decrease" amounted to 236,113 or 24·85 per 1,000.

The causes to which these results are attributed are summarised by the Sanitary Commissioner as follows: severe and wide-spread famine, with all the "hard conditions of life" connated thereby, unsuitable and deficient nourishment and deficient clothing; epidemics of cholera, autumnal fevers and small-pox; a deficient and contaminated water-supply and the "special unhealthiness of the year due to heavy rain after unprecedented drought." To these may be added the distress consequent on the wanderings of large numbers of sickly and famished people in search of work and relief, which was complicated by the influx of unknown numbers of equally distressed people from over the borders. It will be obvious that the sum of these disturbing factors produced such alterations in the distribution of the population in the different registration areas that the purely local rates recorded afford no satisfactory indications for comparison with normal years, and a comparison with the famine year of 1897 is not likely to lead to useful conclusions, inasmuch as the vital statistics of that year were profoundly affected by the distress in 1896, whereas the two years antecedent to 1900 were a period of renewed prosperity and extraordinary fecundity. Thus it happened that when the people had to face the calamities of the year under review, they were as a body the survival of the fittest in the former struggle, fortified by a period of rest and good nourishment, while at the same time there was a far larger infantile population than in 1897. Here was its most vulnerable point, and we find that the tribute paid by the infantile section was far higher than in the previous famine. Altogether the age constitution of the population was radically altered by the previous famine and the subsequent prosperity, and in 1900 everything was in favour of far greater resistance to the renewed untoward conditions, save only as regards the infantile section. These considerations are supported by the general statistics of mortality, the main features of which are (1) a large excess over the mean, but a decrease when contrasted with the figures of 1897, (2) lower death-rates at all age-periods save the first (under one year) in 1900 as compared with 1897. It is not denied that the arrangements made for the supply of food and shelter and for all measures of amelioration which foresight and the experience of the previous famine dictated operated to a large extent in producing these results, but when all the facts are fairly considered, there can be no doubt that the previous calamity, followed as it was by a period of prosperity, contributed to the comparative immunity of the people in 1900.

Altogether 539,234 deaths were registered against 266,930 in the previous year and 658,822 in 1897, figures which yield ratios per 1,000 of 56·75, 28·09, and 69·34 respectively; it may further be noted that the non-epidemic mortality during 1900 was only 49·31 per 1,000, against 62·94 in 1897, which must be subject for congratulation, whether we look to the measures of relief afforded or to the natural immunity acquired by previous elimination of the most unfit. As compared with 1897 the death-rates were lower in 11 districts and higher in nine, the increase varying from 7·56 per 1,000 in Betul to 73·65 in Sambalpur, and, again, it is to be noted that where the rates had been lowest in 1897, these were, generally speaking, highest in 1900.

Calculated on the obsolete census population, the death-rate of children under one year of age was 580·19 per 1,000 for males and 506·12 for females; calculated on the number of births recorded during the year, the figures are 498·2 and 463·6 respectively. Keeping to the births as the basis, the mortality rates in 1899 were 241·5 and 215·7, and in 1897 they were 407·4 and 391·8 respectively.

As regards the chief diseases to which the people succumbed, cholera accounted for 63,114 deaths (6·64 per 1,000 of population), the highest number recorded since 1869, when a ratio of 10·5 was reached. Small-pox carried off 7,005 individuals, of whom 4,221 were children under 10 years of age, the ratio per 1,000 being 0·74 against a quinquennial mean of 0·42. The unusual concentration of children in relief camps and the influx of unvaccinated persons from Native States might have been expected to promote wide epidemic prevalence of the disease, but vaccination operations appear to have kept it in check.

To fevers were ascribed 272,683 deaths against 153,647 in 1899 and 389,335 in 1897, which yield millesimal ratios of 28·7, 16·17, and 40·98 respectively. The disease "appeared to be of the ordinary malarial type," and was most prevalent, as usual, during and after the rains; no cases of "famine" or relapsing fever were observed, though carefully looked for.

As was to be expected, the death-rate (5·16) from dysentery and diarrhœa was exceptionally high, indeed it amounted to double the decennial mean and to more than four times the rate for 1899 (1·25); it was, however, much lower than in 1897, when a rate of 8·53 was recorded. The figures, however, are so unreliable, and so many of the

deaths really due to these causes were ascribed to fever, that one can only derive an idea of their importance in the death returns from the fact that they were at least twice as fatal as in an ordinary year. The failure of the rains converted all water sources into "stagnant and stinking pools," and the people, deprived of their natural food grains, had to subsist on inferior and less wholesome substitutes.

Among Hindus the death-rate was 49·32 in 1900, against 25·46 in 1899 and 59·72 in 1897; among Muhammadans the respective rates for the same three years were 50·4, 29·87, and 52·61; similarly for other classes they were 99·48, 42·35, and 126·23 respectively, a comparison which is again favourable to the effects of the last famine.

Lastly, it may be noted that the important questions briefly touched upon in this necessarily cursory review of the effects of the famine on the vital statistics of the affected areas have received the most careful and detailed examination, but it is impossible within the limits set to this report to give the results in extenso; some of the main conclusions have been set forth in the prologue to this section and in this sketch of the figures furnished by the Central Provinces, but these should certainly be supplemented by a reference to the Report of the Famine Commission of 1901.

Berar.—This small Province, having a population of between 2½ and 3 millions, is contiguous to the Central Provinces, and the history of the year 1900 is very similar to that just related; a severe famine prevailed in a highly prosperous agricultural community which had never previously known straiter times than those brought about by high prices, and hitherto Berar has been considered free from any great risk of this visitation.

A simple comparison of the main vital phenomena recorded in the last two years will show the enormous fluctuations to which these are subject among a population living close to the soil and vibrating to the capricious processes of nature.

Year.	Births.	Deaths.	Increase or Decrease.
1899	144,034	113,992	+ 30,042
1900	89,302	236,022	—146,720

That is to say, there were 54,732 fewer births and no less than 122,030 more deaths in 1900 than in the previous year. The discussion of the significance of these figures is beset with difficulties owing to the intrusion of the unknown factor of immigration from Native States, and owing to the wandering of the indigenous population in search of work and relief.

The birth-rate, which stood at 50·5 per 1,000 in the previous year, fell to 31·3, the mean of the quinquennium being 39·4, these calculations being made on the census population of 1891; on the recent census figure the ratio for 1900 works out at 32·4, and a reference to the figures given for the Central Provinces will show that similar causes produced almost identical effects as regards the fecundity of the people. The highest district rate was returned by Wun, 34·2, and the lowest by Buldana, 26·9.

The total number of deaths recorded was 236,022, giving a ratio per 1,000 of 82·7 against 39·9 in 1899 and 41·9 the mean of the quinquennium, the increase being general in all districts; Basim, with 110·8, and Buldana, with 95·4, returned the highest death-rates, and it was hither that destitute refugees from Native States chiefly flocked, the lowest rates being 73·4 in Amraoti and 67·2 in Ellichpur.

The excess over the rates recorded in the neighbouring and probably equally affected Central Provinces is largely due to the fact that this was the first famine in Berar; scarcity due to high prices was the worst effect experienced in 1897, and consequently the process of elimination was very imperfectly effected in that year, and the people fell a ready prey to famine and epidemic disease, the death-rate being raised by the mortality among destitute refugees from outside.

From May to October, when conditions were at their worst, the people died at the enormous rate of 111·2 per 1,000 per annum. One of the notable features of this mortality was the severity with which it fell on the most robust age periods—between the ages of 10 and 15 it was nearly four times the normal, while for the combined procreative age periods (10 to 40 years) it was 2½ times the normal average; nothing could more clearly indicate the serious and searching nature of the distress when it is borne in mind that the total death-rate was only about twice the normal.

Turning to the infantile mortality rates, we find them rising from 231 in 1899, with a range of from 196 (in Wun) to 264 (in Ellichpur), to 490 in 1900; in Basim it was 619 and in Buldana 540, showing that in these districts considerably more than half the children born died within the year.

The urban mortality was at the rate of 87·2 against 82·1 in rural areas.

One of the severest epidemics of cholera on record afflicted the famished people, 18,375 deaths being recorded, or 6·4 per 1,000 against a quinquennial mean of 2·4, but the Sanitary Commissioner affirms his belief that probably 10,000 deaths from this disease were registered under other heads.

The mortality from "fevers" rose from 49,938 in 1899 (17·5) to 84·017 in 1900 (29·5); the increase being general in all districts, Wun furnishing the highest rate, 41·3, and Ellichpur the lowest, 20·7. Influenza was present in epidemic form, but there was no "famine" or relapsing fever; towards the autumn the type was definitely malarial, with hepatic complications and jaundice, and these cases were notably fatal.

Dysentery and diarrhœa, which accounted for 20,263 deaths in 1899, were reported to have caused no less than 63,860 deaths in 1900, this enormous increase being ascribed to the consumption of bad grain, which was removed from underground pits to meet the demand, as also to imported lentils, to which the people were unaccustomed, and to contaminated water.

The rise in the mortality ascribed to "other causes," which amounted to over 50 per cent. on that of 1899, was, it is said, chiefly due to the prevalence of lung diseases which followed influenza, and carried off large numbers of the very young and the very old.

Muhammadans, a very small section of the population, died at the rate of 66·8 per 1,000, against 36·4 in 1899; the rate for Hindus was 81·3, against 40·0 in 1899; for Christians, 128·9, against 27·1; and for Other classes, 140·1, against 44·4.

Madras.—The total number of births recorded during the year was 1,049,199, against 1,048,335 in 1899, and the ratios per 1,000 on the old census population are 31·8 and 31·3 respectively; it is at present impossible to say how the new census figures will affect these rates, as although the provisional total has been furnished, an unknown number, some two or three millions, are not under registration; it may, however, prove that the true birth-rate for the year is just under 30 per 1,000, the quinquennial mean being 29·3.

The birth-rate has shown a consistent tendency to rise throughout the decade to an extent not altogether due to the increase in population, and this must be attributed in part to better registration, a matter for which there is still room for considerable improvement. For here we have a large Indian population (some 35 millions in all) with a birth-rate on the estimated population, ranging during the last 10 years from 22·0 to 27·4 per 1,000, and yet increasing at a substantial rate. The recorded death-rates on the census population have similarly varied from 19·3 to 26·2 during the same period, so that if these figures could be accepted, the natural increase would be accounted for. Such low death-rates, however, at once throw doubt on the reliability of the registration returns, and a study of the statistics raises the strongest presumption that both births and deaths are gravely understated.

This is, indeed, the opinion of the Sanitary Commissioner, who last year affirmed that in the opinion of the registration agents the birth of an infant who did not survive the first year of life was often deemed unworthy of record, and again, on the other hand, "there is a tendency to ignore the deaths of infants." The low birth and death-rates and the wide range of variation in the rates in different areas are the outstanding features of the vital statistics of this Presidency, and obviously the pressing need is a reform in registration. To this end the new Act for compulsory registration of vital phenomena in villages was brought into partial operation towards the close of the year under review, 400 village communities being included in its scope as a first step, and it is scarcely too much to hope that surely, if slowly, a complete revolution in the character of the statistics may be looked for.

The City of Madras stands first, as usual, with a birth-rate of 46·1, and is followed by Chingleput District (near Madras) with 40·2, while the rates for Nellore and Cuddapah fall to 27 and 26·5 respectively, the urban average being 36·9, against a mean rural rate of 31·4. Where the birth-rate fell off in comparison with the previous year it is generally attributed to the effect of high prices inducing scarcity, which in four districts bordered on famine.

The deaths recorded in 1900 aggregated 770,859, or 23·4 per 1,000, against 675,094, or 20·1 per 1,000, in 1899, and a quinquennial average of 21·3. All save four districts shared in this increase, which is attributed chiefly to the unusual mortality from fevers and bowel complaints. The highest death-rate was recorded by Madras City (46·8), followed by the Nilgiris (34·4), while at the other end of the scale, Ganjam had a rate of 16·4, and for three other districts it was below 20 per 1,000. The average urban rate was 32·6, against only 22·6 in rural circles.

The infantile mortality rate, calculated on the births, rose from 159 in 1899 to 164·9 in 1900, with a range of from 115 in Malabar to 282·8 in the Nilgiris. An average rate which is less than that of France is obviously open to more than suspicion.

The death-rates recorded against the different sects are as follows:—Hindus, 23·5, against 20·3 in 1899; Muhammadans, 22·3, against 18·6; Other classes, 11·2, against 23·6; and Christians, 22·1, against 16·3 per 1,000.

The details as to the chief causes of mortality will be found in the subsequent section.

Coorg.—Under the instructions recently issued by Government for the condensation of reports, the materials furnished this year from the small province of Coorg are extremely meagre, and, indeed, consist, so far as at present available, of the bare tables of statistics. From these it appears that the total number of births recorded during 1900 was 4,542, or 26·25 per 1,000 of the population, the previous year yielding 4,427, or 25·59 per 1,000, and the mean for the quinquennium being 23·0.

The aggregate number of deaths, which was 4,845 in 1899, a ratio per 1,000 of 28·0, rose to 6,302 in 1900, or 36·42, as compared with an average for the previous five years of 33·04. The urban rate was 52·48, against 34·83 in rural areas. No fatal case of cholera was recorded during the year; small-pox accounted for 314 deaths (1·81 per 1,000), which is twelve times the average for the quinquennium; and for the rest it may be said that to "fevers," which carried off 4,840 persons, 77 per cent. of the total mortality is ascribed. The infantile mortality rates, calculated on the births, were 318 for males and only 260 for females, which suggests that many of the deaths of the latter are unrecorded.

Muhammadans died at the rate of 37·19 per 1,000, Hindus at 35·7, and Other classes at 65·44 per 1,000.

Bombay.—The history of this Presidency in 1900, as disclosed by the vital statistics, is a pitiable one, and all the more so that it is the climax of a long period of distress and retrogression due to the prevalence of pestilence and famine. The deaths exceeded the births in the year under review by no less than 813,121; the death-rate rose to 70·07 per 1,000, which is by far the highest on record, the highest annual rate during the previous 20 years having been 39·84 registered in 1897.

The birth-rate, on the other hand, was the lowest on record, having fallen from 36·42 in 1899 to 26·87, the decennial average being 35·32 per 1,000.

There would be nothing gained by contrasting the rates of the different local areas, or by instituting comparisons with previous years; famine or dire scarcity prevailed everywhere, save in the southern registration division embracing only four districts; and throughout the Sanitary Commissioner's report one is constantly baffled in trying to arrive at definite conclusions by the extraordinary movements of the population which are incidentally referred to. Famine drove large numbers to relief camps and raised the rates in poor-houses included within municipal limits; plague is said to have caused movements in the opposite direction, *viz.*, from the towns to the rural areas, to escape the sanitary regulations. Cholera caused large numbers to fly panic-stricken from one place to another, and beyond these inter-provincial ties there was probably a considerable outflow of emigrants. And this complex movement of the people has probably been to some extent in operation for the last few years, so that all deductions based on the distribution of the population in 1891, on which the rates are calculated, are subject to fallacies it would be impossible to avoid.

In 1899 the number of deaths recorded was 672,269, a ratio of 35·72 per 1,000; in 1900 the figures rose to nearly double, *viz.*, 1,318,783 and 70·07 per 1,000 respectively. This enormous mortality is referred to the different chief causes in the annexed statement.

which also affords a comparison with the mean of the quinquennium 1891–95, when normal conditions may be said to have prevailed.

—	Quinquennial mean, 1891–95.	1900.	Increase.
Cholera	24.416	163,889	139,473
Small-pox	2,656	9,885	7,229
Fevers	397,211	543,319	146,108
Plague	Nil	33,196	33,196
Dysentery and Diarrhœa ...	35,223	218,243	183,020
Other causes	91,053	342,027	250,974
		TOTAL EXCESS ...	760,000

Criticism is baffled in face of these figures, and moreover the Sanitary Commissioner furnishes evidence that they fall short of the truth. At the same time it is to be noted that of the total excess (762,298 deaths) no less than 610,959 deaths are distributed between two registration divisions only, the Western and the Gujarat ; in the former the death-rate is 82·96, and in the latter 156·47, per 1,000, and it was here that the effects of famine were most severely felt.

Cholera is dealt with in the subsequent section. The mortality from small-pox was the highest on record for the past 10 years, and the circumstances under which the people lived afford a sufficient explanation. The total number of deaths, given above, is equal to a ratio of 0·52 per 1,000 against a quinquennial mean of 0·12 ; in the City of Bombay it was 3·71, largely due to the influx of destitute refugees.

The deaths from fevers gave a ratio per 1,000 of 28·87 against 12·14 in 1899 and a decennial mean of 20·57, and this latter includes the plague deaths registered from 1896 to 1899. The mortality was greatest in the famine areas, and notably in Gujarat, in two districts of which the rates rose to 111·27 and 167·77 per 1,000, but these figures certainly include very many deaths from other causes. A careful investigation failed to produce evidence of relapsing fever save in Bombay City, where this disease has been endemic for years.

The deaths ascribed to dysentery and diarrhœa are equal to a ratio of 11·59 per 1,000 against a quinquennial mean of 3·07.

" The consumption of badly cooked or of raw grain, of grain to which the people were unaccustomed, and even of wild seeds, leaves and roots, . . . these are the chief causes, along with a deficient and contaminated water supply, of the epidemic of dysentery and diarrhœa."

The extraordinary rise in the mortality from " other causes " is attributed to the prevalence of plague, " which has made registrars careful not to put too many cases down to fever, which attracts enquiry " ; to famine ; and, to some extent, to improved registration.

The death-rate among Muhammadans was 43·59 per 1,000 against 26·98 in 1899 ; among Hindus, 77·36 against 38·12 ; among Christians, 52·64 against 38·66 ; among Parsis, 35·74 against 32·06 ; and among Other classes, 20·20 against 12·74 per 1,000 in the previous year.

Burma.—The annals of this province for the year 1900 afford a striking contrast to those of the peninsular areas it has just been our melancholy duty to discuss.

The extraordinary increase in the population during the decade has been alluded to in the prologue to this section, and though the facts as to immigration have not yet been disclosed, it cannot be doubted that the " natural increase " has played a predominant part in the result.

The total number of births registered in Lower Burma, which was 165,229 in 1899, a ratio per 1,000 of 37·04, rose to 171,183 in 1900, or 38·37 on the old census figure, against a quinquennial mean of 32·86. On the new census population the births recorded in 1900 give a millesimal rate of 31·8, and this is only one indication that the efforts made to register the simple vital phenomena are only very partially successful. This is a matter which is receiving the careful attention of the authorities, and a high standard at this stage of our relations with a comparatively recently acquired province and a shy people could scarcely be expected. The rates vary from 48·17 per 1,000 in Sandoway district and 47·96 in Pegu and 47·12 in Hanzada, to 32·93 in Akyab, 31·95 in Thaton and 17·43 in Rangoon City, the last result being largely due to the relatively small female population and to the floating nature of a large proportion of the whole population, this being the gate of Burma by which large numbers of emigrants enter.

The average urban rate is 27·55 against 39·06 in rural areas, the former being lowered by the very unequal sex-distribution of their population in many of the towns. For all this there are signs of greater care in registration in the rural areas than in the towns, and when the average rate in the 13 selected towns in Upper Burma (which can legitimately claim more indulgence) is found to be 36·87 per 1,000 of their population, the case for more energy in, and more stringent scrutiny of, the work of registration in the towns of the lower province is emphasised.

The record of births in Upper Burma is confined to 13 selected towns, the rate for which has been given.

The total number of deaths registered in Lower Burma was 122,714 against 121,771 in the previous year; the ratios per 1,000 on the census population of 1891 being 27·51 and 27·30 respectively, and the quinquennial mean 25·14. If the rate for 1900 is calculated on the new census figure, it amounts to only 22·8, which is scarcely consistent with the evident probabilities, with the evidence of defective registration which an examination of the statistics discloses, notably the wide range of variation in the total rates and in the infantile mortality rates.

The districts of Kyaukpyu and Myaungmya furnish death-rates of 33·31 and 33·20 respectively, while that for Rangoon City is 42·39; on the other hand the Mergui rate is 21·49, that for Thaton 21·34 and that for Prome only 19·59. In the towns the death-rates range from 48 per 1,000 in Myaungmya to 16 in Prome, the average urban rate being 32·7, while that for rural areas is 26·71.

Calculated on the births, the infantile mortality rates ranged in the five different divisions from 207·9 in Arakan to 135·14 in Tenasserim, figures which indicate approximately the attention paid to registration in the two areas. At the best the rates must be held to be gravely inaccurate, and when they are worked out for males and females separately, still greater anomalies are exposed. For instance, in Amherst district the female infantile mortality rate is only 83, and in Mergui only 97, and it is quite evident that while the deaths of many infants of both sexes are lost to account, the error is gravest as regards the females.

In Upper Burma, while only 13 selected towns return birth statistics, deaths are registered in a larger area comprising a population of about 2½ millions. The total number of deaths recorded in 1900 was 53,496, a ratio of 21·8 per 1,000, against 51,615 and 21·03 per 1,000 in the previous year; no quinquennial mean is available for comparison. The average rate for districts was 21·8 per 1,000, ranging from 32·91 in Kyaukse to 13·96 in Myingyan; the mean rate for towns was 32·83, and for rural areas 20·19. Registration is of so recent institution that further discussion of these figures is unnecessary, but it is hoped that, if only for purposes of education, the area under registration in the upper province will soon be extended, and this might, it is thought, be done forthwith as regards the births, if only to assimilate the population under registration for both births and deaths.

The incidence of mortality from the chief causes presents no special features of interest, the figures under each head approximating fairly to the average.

As regards the incidence on the different sects in Lower Burma, the record is as follows:—Hindus, 39·04 per 1,000; Burmese and Buddhists, 27·38; Muhammadans, 24·6; Other classes, 31·85; Europeans and Eurasians, 17·31; all these rates showing very little variation from those of the previous year.

History of Chief Diseases.

Cholera.

The distribution of cholera in India in 1900.—The mortality from cholera, which in 1898 and 1899 had been the worst on record during the eighteen years then concluded, rose with an appalling bound in 1900 to the highest total of which we have any authentic record. The number of deaths recorded in British territory, which was 152,703 in 1898, giving an average ratio per 1,000 of the total population under registration of ·70, rose to 171,410 in 1899 (ratio per 1,000 ·78), which, however, is considerably less than the average annual mortality in the single province of Bengal. In 1900 the number of deaths registered reached the enormous figure of 797,222, equal to a ratio per 1,000 of 3·7 as compared with the quinquennial mean of 1·5. If the returns from Native States be included, and if defective registration be allowed for (and many deaths from this cause escaped recognition or were returned under other heads in the tracts affected by famine), there can be no doubt that the true aggregate number of victims exceeded 900,000.

This exceptional prevalence of the disease was very generally, if not equally, distributed all over India Proper, but in Burma the mortality was considerably less than the average. It will be remembered that an exceptional feature of the epidemicity of cholera in 1899 (see report for that year) was the abnormal incidence upon the last quarter, no less than 44 per cent. of the total mortality falling within that period, and the months of November and December ranked first in point of unenviable precedence. Deaths were reported from all provinces in December—except the very small areas of Ajmer-Merwara and Coorg—and in numbers generally in excess of the normal prevalence at this time of the year. Only five districts out of 46 in Bengal and only two out of 11 in Assam were reported free of fatal cases in December; nearly one-third of the districts of the North-Western Provinces and Oudh and of Madras were infected, and serious outbreaks were reported in three of the districts of the Punjab; Bombay and the Central Provinces alone were comparatively free, though three districts in the former and two in the latter reported deaths in the last month of the year.

Deaths from Cholera in the different Provinces in India from 1877 *to* 1900.

‖ Excluding Zamindaries.

The *materies morbi* was, then, extraordinarily widespread at the commencement of the year under report, and it only required a continuation of favouring conditions of environment and a susceptible population to produce the results we have to deplore. And, so far as our present knowledge enables us to indicate and appraise the favouring conditions, they were abundantly forthcoming. It would be difficult, as of course it would be fallacious, to endeavour to summarise in a sentence the general meteorological features of the year over the vast area of this continent, but generally speaking it may be said that the monsoon ceased exceptionally early in 1899, and that the conditions thus produced were intensified by the comparative lightness or absence of the winter and spring rains and by the late onset of the great monsoon in 1900. Looking no further than to the effect thus produced on the drinking-water supplies, which for the enormous majority are drawn from superficial sources (rivers, open "tanks," and shallow wells, all within, or close to, crowded inhabited sites, and almost invariably subject to gross pollution), it is not difficult to follow the course of events produced by prolonged drought among a population as careless, ignorant, and fatalistic as that of India. The supply of one of the prime necessities of existence—and the most imperative—was cut off at innumerable habitual sources, causing an overwhelming call on those that remained which were for long months at their lowest ebb, and subject to all the deteriorating influences of stagnation, and to greatly enhanced risks of pollution. Add to this the widespread presence of the specific agent of the disease, and it is difficult to understand how any but the naturally immune escaped the penalty of infection. Briefly, the number of available sources of water-supply was enormously diminished, while those that remained were exposed to inevitable specific pollution, and radiated a far wider malign influence in proportion to the greater call made upon them. Scarcely any precautions would avail against such conditions; counsels of perfection are frequently a bitter mockery to those for whom they are proposed, and surely to the enormous mass of the famine-stricken and to the majority who were not far from famine, advice to boil their drinking water would have come with the force of the bitterest mockery.

The districts which were infected at the end of the previous year, and those which suffered most during 1899, were, generally speaking, those in which the disease first assumed epidemic force in 1900. Then month by month as the unfavourable conditions developed, as the drought became more intense and widespread, and as scarcity became famine over large tracts,* the mortality rose steadily or by bounds, the result being that although the prevalence of the disease varied considerably in different areas with the sum of the conditions that go to favour its propagation, yet it may be said that only nine districts within the bounds of British territory, from which alone approximately accurate records are received, were entirely free from fatal cases throughout the year.

This brief general survey may conclude with an allusion to cholera in Native States and in the neighbouring territories of Afghanistan and Baluchistan so far as the imperfect records available permit. In the twenty States included in Rajputana, where registration is very defective, 28,719 deaths were reported during the year, giving a ratio of mortality of 2·4 per 1,000 on the census population of 1891, and a ratio of 2·9 on the population of 1901. Famine was generally prevalent throughout this area, and the more or less aboriginal tribes (Bhils) suffered very severely.

In the States comprised in Central India, 18,545 deaths were reported, giving a death-rate of 1·8, but here as in Rajputana there can be no doubt that many deaths escaped record.

In the seven cantonment stations in the Hyderabad State from which reports were received, there were 3,813 deaths registered, which yield a ratio of 10·4 per 1,000 on the aggregate population. In all the above three areas the disease may be said to have first appeared in March or April and to have attained its greatest intensity in May, June, and July, with the culmination of the heat and drought, and to have died out in October after replenishment or reinforcement of the scanty water sources and the fall of the temperature.

In June the Government of India received intimation of an outbreak of cholera in the Khyber area of Afghanistan, and a little later, authentic reports of a widespread and virulent epidemic in other parts of the country, Kabul itself suffering severely. The disease appears to have disappeared in September, at any rate in its epidemic form, but no official record is available. The facts as to an epidemic in Baluchistan can merely be

* For a more extended reference to the effects of Scarcity and Famine, *see* Section on "Vital Statistics" and the account of cholera in the different Provinces which follows in the present section.

recorded in much the same terms ; the disease was believed to have been introduced by travellers from both India and Afghanistan ; the epidemic was at its worst during June and the three following months.

In August, cholera was reported to have broken out in Kashmir, and its introduction was traced, on reliable evidence, to importation from the Punjab, where the disease was, and had for months been, epidemic. The year closed with the disease still widely prevalent.

The foregoing details may afford a bird's-eye view of a historic epidemic ; we see cholera abnormally prevalent in the true endemic area of Lower Bengal and the Assam valleys at the end of the preceding year. There was in this area a comparative lull, but still widespread prevalence, during the early colder months of 1900, and then following the normal epidemiological course, there was a rapidly progressive rise to the highest development in the hottest and driest period preceding the monsoon, no marked depression occurring until the rains were well established. Beyond this area as we move westward the maximum prevalence is, as usual, found to be later and coincident with the first rainfall, the epidemic tide rising to its highest in the North-Western Provinces in June and in the Punjab in July, while at about the same time it pursues its ravages in the trans-frontier territories, and then flows into Kashmir.

The Madras epidemics pursue their normal characteristic course, subject to the influence of the two monsoons, a matter to which attention was directed in the last Annual Report.

General considerations on the subject of cholera and sanitation in India.—Before reviewing the most prominent features of cholera prevalence in the different provinces, it is impossible to refrain from a few remarks on the significance of the facts summarised. Taking the last four quinquennial periods, it cannot be said that any appreciable effect has been made upon the death-rate from this disease among the general population. While the mortality among British troops and the prisoners (with a daily average strength of 75,000 and of a little over 121,000 respectively) has been steadily reduced (and it must be borne in mind that among these classes registration of death-causes may be said to leave nothing to be desired), cholera comes and goes and leaves its mark upon the general population with a rhythmic intensity and lull that so far has defied our efforts to control it. It is late in the day to affirm that, in a true and broad sense it is "a filth disease," and that its prevalence connotes a failure to secure a certain standard of hygienic righteousness. While allowing for the special difficulty this country labours under from the fact that the causative flora find an indigenous habitat in many parts, the lesson of such epidemics as fall to be recorded here from year to year is plain, if the practical issue involved be one of enormous difficulty. It is true that to some extent the figures recorded have previously been so defective that the improvement which has recently been secured must lead to the impression of a larger comparative mortality. Any comparison with the past is subject to the gravest fallacy, but still it is certain that the figures as they stand are considerably short of the truth. Figures which run to millions are apt to be unduly staggering, and it may be urged that an all-round rate on the total population of less than 2 per 1,000 is a comparative trifle when set against a total death-rate of 30·5 (the mean for the five years ending in 1899 for all India, under registration). But it must be confessed that it has a far deeper significance for the sanitarian and the State. The conditions which favour cholera are similar to those which probably favour the whole class of bowel complaints, which doubtless claim something like one-third of the total harvest of death in India, though the imperfect records fail to exhibit them in this light. While laboratory research will doubtless elucidate many of the epidemiological problems, the cardinal principles of prevention were firmly established before the discovery of the true living agent, and we know that in Sir John Simon's words that this is a "disease against which there may be found security in the cultivation of public and private cleanliness ;" . . . "such cleanliness as consists in the perfect adaptation of drainage, water-supply, scavenage and ventilation to the purposes they should respectively fulfil," conditions which may, in this connexion, be summed up in the securing of a pure soil and pure water.

How do we stand in regard to this obligation ? The conditions under which the great bulk of the population lives makes the task of applying our knowledge of the etiology of these "filth diseases" one of extraordinary difficulty. Nine-tenths of the people live under conditions that do not permit of constant effective sanitary control by the comparatively small organization at our disposal. At the census of 1891 only some

27,000,000 souls (less than one-tenth of the whole) were to be found in towns containing a population of 3,000 and upwards, and the larger urban communities alone are subject to constant expert sanitary supervision though efforts have been made, in recent years, to reach the villages. Probably not more than an aggregate population of 5,241,265 enjoy the benefits of a properly conserved public water-supply, and certainly far less than that number avail themselves of it, and this fact at once brings to light the almost ineradicable prejudice for standing upon the ancient ways that has to be encountered in this question of cholera prevention, as, indeed, in every direction.* The result on the water-supply of a calamity such as a failure of the rains has been briefly touched upon. Then as regards pollution of the soil, the almost universally prevalent "trenching system," which probably has no rival when carried out with due regard to all the essential conditions, opens the way to very special and obvious dangers when it resolves itself into dumping filth anywhere and everywhere within and around inhabited sites and near water-sources, as is generally the case. Where adequate knowledge and control are available (as in the larger towns), the difficulties are often insuperable, while, where as in the case of village communities "trenching" might be carried out to the best advantage, the essential knowledge and control are, as a rule, wanting.

In face of these conditions and of the ignorance and apathy which beget them, it is incumbent upon Government to reorganize and extend the sanitary service, to bring it into closer touch with the scattered rural masses and to bring them education and assistance, while redoubling efforts in the larger centres. A scheme to this end doubtless presents difficulties; the "silent deep disdain" of an oriental people must be treated with consideration, and they cannot be dragooned into western methods in matters concerning their private life. There are also financial difficulties in a country which has recently passed through a series of crushing calamities from the failure of several harvests. But it is believed that these difficulties are not insuperable, and that Government is prepared to consider proposals which have been put forward for the reorganization and extension of the sanitary department, which it is hoped will mark a new era in the campaign against the more preventible causes of disease and death.

Bengal.—In Bengal, in 1900, the total number of deaths registered as due to cholera was 345,878 or 4·86 per 1,000 of the population, against 107,678, or a ratio of 1·51 per 1,000 in the previous year, and 65,030 (0·91 per 1,000) in 1898. Previous records of the disease in this its so-called "home" and endemic habitat, afford no parallel to the mortality of the year under review. The disease prevailed severely in every district, in no less than 35 out of the whole 46 the death-rate being in excess of 2 per 1,000; deaths were reported from 33,142 villages (about one-seventh of the total), while it assumed epidemic form in 228 registration circles, or in nearly one-third of the whole number, only 17 circles being exempt against 89 in 1899 and 130 in 1898.

The highest district death-rates were 23·77 in Purnea and 11·74 in Champaran; Cuttack, Palamau, Bhagalpur, Muzaffarpur, Shahabad and Dacca also suffered severely, the rates ranging from 8·48 to 7·1, while in 13 others the range was from 6·25 to 4·0 per 1,000. This exhibits the widespread nature of the epidemic in its most virulent form.

In 19 towns the death-rate ranged from 10·14 (in Kendrapara in Cuttack) to 30·42 (in Daltonganj in Palamau), and in 47 rural areas, from 10 per 1,000 in Madhuban in Champaran to 42·08 and 57·23 in two areas in the Purnea district. The urban mortality as a whole was at the rate of 5·06 per 1,000 against 4·85 in rural areas, where, however, registration is far less reliable.

Assam.—The number of deaths attributed to cholera in Assam was 23,761, a ratio per 1,000 of 4·51 on the census population of 1901. In the previous year 8,380 deaths were recorded, of which more than half occurred in the two last months. When the local distribution of the disease is examined, the fatal pre-eminence of the Brahmaputra Valley area, a constant feature of the reports, is at once apparent. The population of the Surma and Brahmaputra Valleys is approximately equal, but whereas in the former 6,791 deaths

* Take the metropolitan city of Calcutta for instance, which has a filtered water-supply. The Health Officer in his report for 1900-01 says:—"Mud is required for the coating of walls of huts" and for building purposes. "To provide this material holes have been dug in the soil with the result that every little collection of huts or houses contains one or more 'tanks' . . . used for bathing, washing clothes, and even for *drinking* and other domestic purposes. Nothing could be more filthy than the water of these tanks." And again; "in the central part of the town there are not many tanks left, but in all the suburban area the number is enormous. There are still a great number of wells in the town, and the water they yield is not safe to drink." Year by year a number of these tanks and wells are filled up, but the difficulties are very great, and, as the water-supply is not constant, it is not possible to insist on a general measure of filling up.

were reported, giving a ratio per 1,000 of 2·56 and registration is here at its best, in the latter there were no less than 16,970 deaths, or a ratio of 6·47 ; the records show that in only two years has this mortality been exceeded.

The disease fell with the severest force upon the three districts of Nowgong, Darrang and Kamrup, in which deaths were reported from all the registration circles and from about one-sixth of the total number of villages, the mortality giving death-rates of 24·95, 9·6 and 7·35 in the three districts, respectively. Nowgong is on the south bank of the Brahmaputra, adjoining Kamrup and facing Darrang ; it is notoriously the most unhealthy district in the Province. Cholera was present during the last months of 1899, and to about the same extent in January of the year under report ; there was a considerable increase in February and a sudden virulent outburst in March, maintained throughout April, during which two months 4,521 deaths out of the total of 6,529 occurred ; after June, the disease suddenly lost its epidemic character, but deaths continued to occur in each of the remaining months of the year. This is the sixth, and by far the most severe, epidemic from which this district has suffered during the last 12 years, there being an outbreak after a quiescent interval of two or three years in each case.

The particulars afforded of the epidemics in the neighbouring districts of Kamrup and Darrang in 1900 are stated in very similar terms, and the area may be considered one and practically undivided, for the river which courses through is rather a connecting link as regards the propagation of the disease. The Sanitary Commissioner confesses that he is "unable to say to what these repeated outbreaks can be due" * * "the habits of the people are as dirty and insanitary as possible ; they never change for the better, and they could hardly ever be worse." Here we have another endemic area, in an alluvial valley, from which the disease can never be said to be absent, though for considerable periods it assumes a more or less sporadic form. Then at short intervals the conditions become favourable for a wide extension, and we see the disease suddenly assuming a virulent epidemic force, indicating contamination of a common fomites, such as the water-supply, under certain climatological conditions. In this comparatively compact area with a population of a little over one million souls, no less than 10,221 deaths out of the total of 14,103 occurred in the March–June period just before the onset of the rains. Over 20,000 persons must have been attacked in this period, giving an *annual* morbidity-rate of about 50 per 1,000 ! Much as there is to learn as to the conditions of life of the germ in the environment, it is surely not difficult to understand how, given its presence therein, a people whose personal habits are so forcibly described in the words quoted and who depend on surface streams and collections of water, should pay the penalty in this deplorable way.

It is worthy of note that the death-rate among the immigrant coolies on tea gardens was considerably less than that furnished by the general indigenous population, which is quite contrary to the usual results recorded. There were about 662,471 coolies employed in 1900, and of these 2,085 died of cholera, giving a ratio per 1,000 of 3·15. The three districts which suffered severely are important centres of the tea industry, and a comparison of the death-rates suffered by the indigenous population and the garden coolies brings out the comparative immunity of the latter very strongly. In Nowgong, the general rate was 26·7, that furnished by the coolies was 2·3 only ; in Darrang, the rate excluding the gardens was 10·95, and in the gardens 5·17 ; in Kamrup, the rates were 7·37 and 3·99, respectively. Some part of this relative immunity may perhaps be fairly ascribed to the effect of inoculation with Haffkine's "vaccine," while for the rest, there is good reason to believe that the sanitation of tea gardens is receiving a larger measure of skilled attention, a matter for congratulation.

North-Western Provinces and Oudh.—The total number of deaths recorded from cholera in 1900 was 84,960 against 8,142 in 1899, the millesimal rates being 1·81 and 0·17, respectively ; the mortality has been exceeded on five occasions during the last 23 years, but while it is about 2½ times the average for the last quinquennium, it may be noted that the death-rate vies with those of the Punjab and Madras in being the lowest recorded in India Proper during this disastrous year.

In fourteen districts the number of deaths reported did not exceed 107 in any one, and in two others no deaths occurred, so that in about one-third of the Province the disease did not assume a serious form. The highest district death-rate was that furnished by Sultanpur (Oudh), *viz.*, 15·96 per 1,000, while among the towns, Ghazipur stands first with a rate of 4·82.

It is satisfactory to note that the Hardwar and Magh Mela (Allahabad) fairs again passed off without the appearance of epidemic disease, and this must undoubtedly be attributed, in a year like that under review, to the careful and systematic sanitary

measures carried out. Here, indeed, we have the other side of the picture to that touched upon in the remarks on page 89, and one that redeems the record of our efforts from the reproach of futility.

Punjab.—The year 1898 was one of almost total immunity from the disease in the Punjab ; in 1899, the deaths numbered 1,816, more than half of which occurred in two districts, where famine was prevalent. In 1900 the mortality figure rose to 28,260, giving a rate per 1,000 of 1·37, against a quinquennial mean of 0·08 ; indeed, in only one previous year, that of 1892 when the deaths amounted to 75,959, has this mortality been exceeded within the last generation. But there were very special factors in operation to produce this result, as will be seen when it is stated that, of the total number of deaths recorded (28,260) no less than 15,731 occurred in the famine districts of Hissar, Rohtak, Karnal, Ferozepore and Lahore ; in Hissar alone, where famine was at its worst, 6,399 deaths (or 23 per cent. of the whole) were reported, giving a death-rate of 8·25 per 1,000 of population.

With the exception of Hissar and Rohtak, the Province was entirely free from cholera for the first three months of the year. In the two districts named, the epidemic was a continuation of the outbreak of the previous year, and the disease was at first confined to the famine relief camps. It is most unusual for cholera to appear in the Punjab in the winter months, and much must be ascribed to the constitutional effects of famine and the aggregation of debilitated refugees. It is supposed that the source of infection was a tank, the water of which was drunk by these refugees ; the disease spread from camp to camp and subsequently to many towns and villages in the Hissar district. Thence the disease is stated to have been conveyed to a relief camp in the Rohtak district by famine labourers, and next it appeared in a relief camp in the Delhi district, among a gang of lower caste people (sweepers) who had been imported from Rohtak for duty. Next, in April, the disease broke out in Karnal, the first case being furnished by a pilgrim who had just returned from the Hardwar Fair. Thus the disease spread from place to place until in July, 26 of the 31 districts were infected and the epidemic was at its height, 9,711 deaths occurring in this one month, or one-third of the annual total. In August and September, though approximately the same area was affected, the mortality fell off greatly, and thenceforward the disease suddenly abated until in December only one district recorded deaths, *viz.*, Dera Ghazi Khan (17).

In the Punjab we find, as usual, the percentage of villages attacked very small compared with that in the endemic areas ; in Bengal it was 14·8, in Assam, 16·8, while in the Punjab, where famine prevailed widely and refugees were passing to and from nearly all parts of the Province and where also every district was infected, we get only 6·6 per cent. For one thing the water-supply which is largely from deep wells is naturally more easily conserved.

Central Provinces.—In 1898 there were only 7 deaths reported in this area, and in 1899 the number was only 76, a condition of immunity without a parallel in its annals. But in 1900 the mortality was the highest on record since 1869, 63,114 deaths being reported, giving a death-rate of 6·64 per 1,000 against a quinquennial average of 2·65.

The Central Provinces, as is well known, had passed through the ordeal of a very severe famine in 1897, but it is said by the Sanitary Commissioner that " the actual physical famine-producing conditions were much less severe in extent and degree in that year than in 1900." Here then we have again the key to the enormous mortality recorded from a disease which finds in famine its chief ally, and, unfortunately, it cannot be doubted that very many cases escaped registration.

It is said that the infection was introduced on one side into Chhattisgarh from Orissa (Bengal) and the Feudatory States, and into the west from Berar and Indore, and it must be remembered that all these areas were affected and that continuous to-and-fro tides of immi—and emigration were in progress throughout the year, the people seeking escape from both famine and pestilence and large numbers restlessly moving on from one centre of relief to another.

In January only one district was infected, and the same applies to February if we exclude the Mahanandi Zamindaries from which the records are inaccurate. In March the disease spread to the districts contiguous to the Zamindaries, and altogether the death-roll rose to 1,252 from 40 in the previous month ; In April only 8 districts were free, and 7,338 deaths were reported ; the number rose to 11,811 in May and to 20,158 in June, falling to 13,148 in July and to 7,893 in August. Thereafter the disease lost its epidemic character until in November it was practically extinct, no deaths being recorded in December. Its progress in the earlier part of the year " was accompanied by unusual

heat and dryness, for it was not until the second week in July that the monsoon was established"; thenceforth a rapid subsidence of the disease ensued. The Sanitary Commissioner reports that "the most strenuous efforts were made to combat the disease, and were most successful where the water-supply could be controlled; it is a fact worth recording that the disease never really gained a hold in the Public Works camps," though the figure he gives to support this view is open to criticism, possibly due to a clerical error. He goes on to say that during epidemics "all wells, small tanks and *jhiras* supplying drinking water to the affected localities, including famine-relief camps, were systematically disinfected with permanganate of potash, and it is reported that this was generally attended with good results." He furnishes various opinions by medical and civil officers in support of this view and in refutation of the recent tendency to question the value of such "disinfection." It is to be hoped that more definite and reliable facts may in future be obtained as regards the practical utility of permanganate in this connexion, based on simple records maintained at the time, and which it is proposed to issue on a uniform plan.

It remains to add that no less than 8 towns had a recorded mortality from this cause of over 20 per 1,000, the highest rate (37·7) being that returned from a small town in the Sambalpur district. No less than 21·3 per cent. of all the villages were attacked, the disease was therefore widespread, and no object would be served in indicating here the special incidence in different districts.

Berar.—The Hyderabad Assigned Districts have physically many features in common with the Central Provinces, and in 1900 a disastrous famine prevailed; in 1898 the area was entirely free from cholera; in 1899 only 541 deaths were reported, but in the year under review a severe epidemic claimed 18,375 victims, a death-rate of 6·4 per 1,000, which has, however, probably been exceeded on three previous occasions, *viz.*, in 1875, 1878 and 1883. In three of the six districts the disease was present during the last quarter of 1899; it appeared in a fourth district in January, in a fifth in March, and in April all districts were affected. It rapidly assumed epidemic proportions during the hot, dry period, and culminated in July, when 6,452 deaths were reported; the number fell to 2,498 in August, after which the disease died out as rapidly as it had advanced. Registration is perhaps as complete and accurate in Berar as in any area in India, and it is therefore noteworthy that the Sanitary Commissioner believes that "over 10,000 deaths from cholera were erroneously registered under other heads through ignorance, superstition or laziness;" possibly then the aggregate mortality numbered 30,000. It was impossible to trace the source of importation—if indeed we need to assume importation—as famine-stricken refugees from the Hyderabad State and from Bombay had wandered into Akola and Buldana. But, as already stated, the disease was present, many of the water-supply sources dried up and left the rest concentrated and subject to pollution; in addition to this famine stalked through the land. Whenever cholera was reported from a village a hospital assistant or a vaccinator was deputed to "disinfect" all water-supply sources, "and four or five days after this, the epidemic in almost every case ceased. This procedure answered admirably," says the Sanitary Commissioner, "during the cold and hot weather months. When, however, the rains set in it was found impossible to 'disinfect' all available sources, and the villagers helped themselves to any pool or puddle they came across, and these very soon became infected and spread the disease." Still it is noteworthy that cholera rapidly disappeared with a full replenishment of the water sources. In the Basim district, where famine was at its worst and where the total death-rate amounted to 110·8 per 1,000, cholera claimed about one-third of the victims that succumbed to this disease, the rate recorded here being 15·0 per 1,000 from this one cause. All over Berar 18·2 per cent. of the villages were attacked.

Madras.—The total mortality from cholera in 1900 amounted to 60,662 cases, or 1·8 per 1,000 of population (which is about the quinquennial average), against 29,082 cases, or 0·9 per 1,000, in the previous year, which was one of the lowest incidence on record.

The districts of Madura, Tanjore, Tinnevelly and Godavari suffered most, the death-rates therein having ranged from 4·7 to 3·0 per 1,000; all the 22 districts were more or less affected, though two (Nilgiris and South Canara) had only two cases each.

As previously pointed out, the incidence of mortality was heaviest in the districts affected by the south-west monsoon in July, August and September, and in those under the influence of the north-east monsoon in October, November and December. From 49 out of the 61 municipal towns, 5,789 deaths (equal to 2·7 per 1,000 of the total urban population) were reported; Periyakulam with 20 per 1,000, followed by Tinnevelly with 13·8 and Palni with 12·4 being highest; the rate in rural areas averaged 1·8.

Coorg.—As was the case in the previous year, no death from cholera was recorded in this small province during 1900.

Bombay.—The terrible experiences through which the Bombay Presidency passed in 1900, have already been faintly indicated; cholera vied with famine in their devastations, and plague has now become an only too familiar feature in the death statistics. In 1899 only 8,579 deaths were reported from the first-named disease, but the number rose in 1900 to the appalling figure of 163,889, yielding a death-rate per mille of 8·71, by far the highest for any province in India, and nearly five times that of the quinquennial average. The number recorded is fully one-eighth of the total mortality (all causes) for the Presidency, and there is ample evidence that very many deaths from this cause escaped registration.

Every district was affected, though the collectorate of Kanara escaped with only 82 deaths; but the epidemic fell with exceptional virulence upon the Gujarat and Western Registration districts where, excluding the City of Bombay (5·27), the death-rates ranged from 10 to 22 per 1,000 of population. In December, 1899, the disease was present in the collectorates of Dharwar and Bijapur and in the City of Bombay, and in January we find the same areas affected with Khandesh in addition. In February and March, beyond a rapid extension in Khandesh, matters were in about the same state till in April the disease had spread to fourteen districts yielding 15,086 deaths. In May the mortality rose to 32,929, and in June to 33,625, Sind having now become infected, and in July, with an aggregate death total of 44,521, the epidemic reached its culminating point, the monsoon rains having been very light and partial until the end of this month. With the second onset of the monsoon and during August and September, though all districts were affected, the mortality fell off markedly, the former month yielding 23,123 deaths, and the latter only 4,924, the subsidence continuing until in December there were only 488 recorded, and these from nine districts, the Gujarat area having been practically free from October.

For the most part the epidemic fell with the greatest force upon the famine-stricken areas, and on those centres to which the necessitous refugees flocked. Out of 220 rural circles, 201 were more or less severely affected, and in 58 the death-rate exceeded 12 per 1,000, the highest rate recorded (in Vada in the Thana District) being 39·67. Of 56 town circles 51 were attacked, and 29 of these recorded rates of 10·47 and upwards, 12 being in the Gujarat Registration district. The town of Borsad (population 12,159) in the Kaira collectorate suffered the appalling death-rate of 126·9 per 1,000 of its population.

The affected area included 8,461 out of the 25,143 villages in the Presidency (33·8 per cent.), but in Karachi district the percentage affected was as high as 87·7; in Hyderabad it was 66·9; in Kaira, 50·7; in Broach, 50·1; in Thana, 47·9; in Surat, 43·5; and in Satara, 42·5.

The officers of the sanitary department record similar impressions as to the causes that led to this deplorable mortality; they refer to scanty and polluted water-sources, to insufficient and unsuitable food ("badly cooked or raw grain, wild seeds, leaves, bark of trees, roots, &c.," and, in some cases, the flesh of animals that had died of disease), and to the fact that crowds of beggars and wanderers left their homes to seek relief in the larger villages and towns, thus disseminating the disease and its readiest victims broadcast. Again, when the disease broke out on relief works or in camps, a stampede frequently followed which it was impossible to control. Nothing, surely, is wanting to such a picture of accumulated horrors, or to account for the results.

Burma.—There were altogether 3,481 deaths from cholera recorded in Burma during 1900, of which 41 only were reported from the Upper province; the death-rate per 1,000 in Lower Burma, 0·77, is below the quinquennial mean (1·09). The highest mortality was returned by the Thongwa, Mergui and Myaungmya districts, with 2·75, 2·38 and 2·28 per 1,000, respectively. The urban rate exceeded the rural, as is usual, owing partly to density of population and partly to better registration. Sixteen of the 34 town circles and 6 per cent. of the villages suffered. "Civil Surgeons submitted detailed reports of the outbreaks in their districts, but these reports bring nothing new to light as regards the origin or spread of the disease, and it would serve no useful purpose to review them here. An impure or infected water-supply was generally associated with these outbreaks," and the seasonal incidence was chiefly upon the hotter, drier months, ending with the onset of the monsoon.

Cholera among the Troops and Prisoners.—This year (1901) it has been decided that no detailed summary of the "cholera registers" should be given in this place, though the facts disclosed have been used for instruction and the promotion of remedial action where such has been indicated. No fresh light has been thrown upon the etiology of the infection, though the lessons to be derived from the facts summarised in this section from year

to year have been confirmed. The Government of India has recently issued orders for the discontinuation of the "cholera register" which the medical officer concerned has hitherto submitted. This is one of the results of the deliberations of a committee entrusted with the task of examining the value of the numerous returns and reports furnished on all matters concerning the health and the economy of the army in India. This, of course, does not imply the abolition of records of cholera outbreaks in future, but these will take a different form, and it is the intention to revise and codify the general lines on which a single cholera report for each outbreak is to be drawn up in future, while it is hoped to direct attention to all the more important questions of the etiology of the disease. It is confidently anticipated that with the facilities provided by the new command laboratories, more exact and scientific data will take the place of vague guesses and opinions on this subject, and that, starting from the broad general conclusions established, a new departure based on more exact methods of research will be made. At this point, then, the broad facts and the incidence of the disease on the troops and prisoners will be briefly stated, concluding with a short summary of the main indications they afford.

Cholera among British Troops.—In last year's report only one fatal case of cholera fell to be recorded for the year 1899 in the whole European Army in India. It could not be expected that such phenominal immunity should be maintained during 1900, when the disease was almost everywhere at its maximum epidemic prevalence, and when, consequently, the troops were surrounded by foci of infection. Under these circumstances it is matter for some satisfaction that the total number of cases recorded among all ranks of the European troops was 107 with 88 deaths, a case mortality of 82·2 per cent., while among all classes of followers there were 101 cases and 68 deaths, or, altogether, 208 cases and 156 deaths. These were reported from 28 communities (station hospitals, regiments, and batteries) in 28 different stations. The death-rate on the aggregate average strength of the troops (excluding followers) was therefore only 1·45 per 1,000 against 3·70 per 1,000 for the general population, and as we have seen the latter must be accounted short of the truth owing to defectiveness of registration. In many stations where cholera prevailed in the surrounding communities no case was recorded among the European troops or followers.

Cholera among Native Troops.—The returns show that 112 bodies of men located in 76 separate cantonments or camps were attacked during the year 1900. There were altogether 641 cases, of which 390 proved fatal among the rank and file of the native army, while among the followers, &c., there were 409 cases and 212 deaths: that is to say, altogether 1,050 cases and 602 deaths. Calculating the total mortality on the aggregate average strength, the death-rate among the troops (excluding followers) was 3·16 per 1,000, against 3·70 per 1,000 for the general population. In many stations contiguous to or surrounded by communities in which the disease was present among the general population no case occurred among the troops or followers.

Of the total number of cases and deaths recorded it may be noted that not far short of one-half occurred in the Punjab, and fully one-third of the whole in the North-west Frontier stations and outposts. In Kohat alone there were 314 cases with 151 fatalities, to which five regiments, one infantry depôt and two mountain batteries contributed.

*Cholera in the jails.**—Among the jail population with an aggregate strength of 116,408 there were 515 cases of cholera, of which 286 terminated fatally, giving a death-rate of 2·5 per 1,000 of population against 3·7, the rate for all India under registration. In all, 70 different jails were affected, of which six were in Burma (34 cases and 21 deaths); one in Assam (one fatal case); twenty-seven in Bengal (191 cases and 101 deaths); six in the North-Western Provinces and Oudh (14 cases and eight deaths); five in the Punjab (35 cases and 14 deaths); seven in the Bombay Presidency (128 cases and 67 deaths); two in Berar (14 cases and 11 deaths); nine in the Central Provinces (63 cases, 43 deaths); six in Madras (33 cases, 20 deaths); and the Ajmer Jail, in Rajputana, which reported two non-fatal cases. If the death-rates afforded by these fatalities, calculated on the annual average strength of each provincial group, be compared with those of the general population of the province in each case, it will be found that in only two cases did the jail rate exceed that of the province; *e.g.*, in Burma the jail rate was 1·7 per 1,000 against the provincial rate of 0·77, and in the Central Provinces the rates were 7·6 and 6·64 respectively; in Bengal they were approximately equal. But it has to

* The figures differ from those in the statement on page 65, as in the former data are given for subsidiary as well as for central and district jails and for *all* the cases of cholera that occurred.

be remembered that while the jail rate is absolutely accurate, that recorded for the general population is subject to a grave error of defectiveness. In Assam the jail rate was less than one-sixth of that of the Province ; in the North-Western Provinces only about one-ninth ; in the Punjab a little more than half ; and in Bombay Presidency about one-half of the general provincial rate. When the fact that the disease was present in every district, and when the disadvantages incurred by an aggregation of individuals in jails are considered, and, in addition, the low standard of physique and resistance of the criminal population, the results may fairly be deemed satisfactory and to represent the results of the care bestowed on all matters of hygiene.

Summary of alleged causes.—Still, when we come to investigate the evidence afforded as to the causes to which outbreaks among the troops and prisoners were attributed, there are admittedly facts which indicate that in some cases much remains to be done in this respect. In last year's report the state of the drainage of the Mian Mir cantonment was referred to, and this is again the subject of animadversion ; but what is perhaps of far more urgent importance is the necessity of extending the pipe-water supply to the native lines in this station. The danger arising from the open irrigation channels in Kohat has been alluded to ; these are examples of a small minority of cases where reform is urgently called for.

For the rest we have the universal prevalence of the disease in its worst form, and nearly every community was situated in a centre of contagion. In the majority of cases the outbreak was traced to polluted water obtained outside the regular supply provided, in villages, bazaars, and elsewhere when the men were "out of bounds." In a few cases attacks were attributed to a too liberal diet of raw fruit and vegetables or to milk obtained as a rule from places known to be infected ; the carriage by flies of the virus into the institution attacked is suggested in no less than five cases as the most feasible hypothesis.

In the great majority of instances the first cases had had direct personal communication with an infected environment ; among European troops the first attacked were those who had been "out of bounds" ; among native troops sepoys returning from leave and travelling through an infected area, and among prisoners, admissions from infected areas, and first attacks among those on duty outside the jail, introduced the infection as a rule.

The one other established fact as to which the records leave no doubt is the efficacy of movements from the infected site ; in the majority of cases this measure was adopted with almost immediate and conclusive results.

Lastly, it may be noted that of the total number of attendants on the sick, among troops, followers, and prisoners, only 49 persons in all were attacked with the disease, a ratio of 1·7 per cent.

Anti-cholera inoculation.—In the year 1899 the total number of operations performed at the Purulia depôt in Bengal, the only place where inoculation is systematically carried out, was 2,388 ; in 1900 the number rose to 13,291, and the subjects were all emigrants proceeding to the labour districts of Assam and Cachar.

It is, to say the least, unfortunate that the duty of furnishing returns of cholera cases and deaths is not made incumbent upon the employers of these labourers ; it is now permitted to be optional, and returns were received from only five gardens. This is a matter to which attention will be directed, as it is obviously desirable from every point of view that the results of inoculation should be ascertained with some approach to accuracy, and that its efficacy be established or refuted. The only material available for the year under review as a contribution to this question is the record furnished from Goalundo. Of 1,527 uninoculated coolies who passed through Goalundo from April to June, 32 or 2·09 per cent. were attacked by cholera, of whom 17 died ; while among 873 who had been inoculated there were only two cases (0·22 per cent.), both, however, fatal.

A study of the effects of inoculation.—A most interesting series of observations made by Captain Lamb, I.M.S., of the Bombay Research Laboratory, and Major Buchanan, I.M.S., on the effects of inoculation on a large number of prisoners in Nagpur Jail will shortly be published in a forthcoming issue of the Scientific Memoirs (new series) by officers of the Medical and Sanitary Departments of the Government of India, but the results may briefly be summarised in this place :—

(*a*) A preliminary injection of a dead "vaccine" a few days before the living material is inoculated has the effect of causing the constitutional disturbance which follows the latter inoculation to be more severe than when no such preliminary injection is employed. The larger the dose of dead material the greater is the reaction following the injection of the living vaccine.

(*b*) Women exhibit a greater constitutional reaction than men.

(*c*) A slight increase in the amount of living material used causes a great increase in the severity of the constitutional reaction.

(*d*) A previous attack of cholera, recovered from a fortnight to a month previously, has the effect of decidedly lessening the constitutional reaction following a dose of living cholera "vaccine."

(*e*) Finally, an endeavour was made to appraise the effect which these inoculations had on the weight of the inoculated when compared with the ordinary fluctuations in the weight of the uninoculated, and the figures presented show that no appreciable difference in this respect can be demonstrated between the two classes.

Small-pox.

The mortality ratio of India from small-pox rose in 1900 by 75 per cent., but was slightly lower than the quinquennial ratio. All the months of the year, but especially the earlier, showed a greater number of deaths. The total number of deaths in the preceding year had been 53,347. In Lower Burma the epidemic which started in 1898 is now abating. Thirteen cases were detected in the Port of Rangoon—the number of deaths is not stated. In the rural areas of Upper Burma compulsory powers are wanting for the protection of the people, and the law, as it stands, has no authority to prevent the inoculator disseminating the disease, and keeping up a source of contagion which infects the towns by importation. It is believed that small-pox is in a fair way of being eradicated from Assam. The Bengal mortality from small-pox was, as usual, highest in Orissa, Cuttack alone returning more than one-third of the total deaths recorded under this head in the whole province ; and this severe local prevalence of the disease is said to be attributable to the aversion of the people from vaccination and their preference for inoculation. Only three cases, of which one proved fatal, were detected by the Port Health Officer of Calcutta. That the urban mortality was greater than the rural is an unusual feature of 1900 in Bengal; but all the other provinces, except Burma, Madras, and Mysore show the same. The ratio of the North-Western Provinces and Oudh is the lowest on record, and no district, except Aligarh, had more than 100 deaths. Into the Central Provinces the disease made its entry from the Bombay side, and invaded every district but one. The Sanitary Commissioner was able to secure the vaccination of no less than 28,160 children among the large numbers collected in the famine relief camps. In Berar the badly vaccinated district of Wun suffered most. The Sanitary Commissioner of Madras insists that until vaccination is made compulsory in rural areas, more satisfactory results cannot be hoped for. Although vaccination is appreciated by the bulk of the population, mothers are still reluctant to submit their children to the operation ; and the people are often unwilling to undergo it while the disease is present in their midst. The mortality in Bombay was the highest recorded for the past ten years. No district was free, though some were visited lightly. Both in the City of Bombay and in the districts adjacent the outbreak was much increased by the large influx of strangers. In the City of Bombay over 34,800 vaccinations and revaccinations were performed. With regard to Gujarat it is said that, considering the enormous influx of people from surrounding states during the famine, the number of deaths was not large, which testifies to the good work done by the vaccination staff. As to the Port of Bombay, it is stated that there were 1,392 cases of small-pox, against two in the previous year, detected at the outward and inward inspections and on board the vessels lying in the harbour. The number of deaths is not stated.

* Excluding Zamindaries.

Plague.

For India as a whole there was a decided decrease in plague mortality. The decrease took place principally in Bombay, Madras, and Hyderabad State; while the greatest increase was in Bengal. Assam and Coorg remained unaffected, and Central India recorded no mortality.

The main points of interest with regard to plague have been dealt with so fully in Chapter III. of the Report of the Indian Plague Commission, that it is not necessary to touch upon them here, but the following are a few jottings :—

Sputum. Persistence of the bacillus.—Gottschlich in Egypt found virulent bacilli up to the 76th day in the sputum of a man who had recovered from plague; in dried sputum the bacillus was still virulent for a month; in the peritoneal exudation of guinea-pigs for three weeks; in dried-up urine only for three days, because urine dries very thoroughly; in old agar cultures for 8½ months; in the buboes of corpses for 12–16 hours; in the buried bodies of guinea-pigs for three, but not five, days; in the organs of dead animals for 24 hours, but not for two days; in the sputum of a pneumonic-plague patient kept in a covered spittoon in darkness at 25 deg. to 28 deg. C. for four to ten days. On the other hand, Métin's experience was that the sputum was innocuous when ten days had elapsed from the complete fall of the fever and the disappearance of stethoscopic signs; while Schottelius states that when the bacilli become generalized (septicaemia) they may be found in the sputum even of non-pneumonic cases. Rosenau in America kept the bacillus alive for 75 days in the dry state, but confesses that complete dessication was not attained; and Schultz states that when kept cool and sheltered from light, it can preserve its life and virulence for four years. Rosenau's experiments are said by him to show that the plague bacillus is not a frail organism, that temperature is the most important factor in its viability, that moisture favours its life, that sunlight kills it in a few hours, that its virulence is often lost before its vegetability, that clothing, bedding, and food products may carry the infection, that the organism may live a long time in water, &c.; and Sata reports that in dead bodies and earth most of the bacilli perish, but that those which survive become gradually more virulent.

Rats and other animals. Insects. Mode of entrance.—From Robertson at the Cape comes the statement that plague occurred and the specific bacillus was found in cats, rats, a ferret, a guinea-pig, a mouse; and that care has to be exercised not to take the bacillus of chicken cholera for that of plague. Thomson in Australia found the bacillus in rats, in a cat, and in a flea from a rat sick of plague. Opinions as to the part which the rat plays vary from that held by Davies that plague is primarily an epizootic disease communicable to man rather than an epidemic disease communicable to animals, to that of Abel who believes that man is the most dangerous spreader of the disease, and points out, as the result of a study of the old literature, that past European epidemics appear to have run their course without any important participation of rats and mice. In this connexion it may be interesting to note that Kitasato and others reporting on the plague in the Japanese towns of Kobe and Osaka, record that out of 291 dead rats examined in the former the plague bacillus was found in only 61, and out of 200 in the latter in only 23. The Australian reports of Ashburton Thompson and others are strongly in favour of rat agency. But, granted that plague-infected rats are dangerous to man, it is difficult to understand how the infection is conveyed. As Ashburton Thompson says, if the rat is required to explain the local diffusion of the disease, another intermediary, the flea, is required to explain the conveyance of the infection from rat to man. This supposed rôle of the insect, first suggested by Simond, appears, especially at the present time, so natural and likely that it is accepted as true by many, including Thompson, Manson, and Klein. On the contrary, Nuttall, Kolle, Galli-Valerio, and others have failed to verify by experiment any such transference of infection; and if it be a reality, there must be some necessary condition in natural infection which has not yet been fulfilled in the laboratory experiments. Kolle has been so impressed with Ashburton Thompson's evidence that he proposes to renew his experimental investigation. Thompson himself in the few experiments he was able to make did not succeed in conveying the infection from rat to rat by means of fleas. In one case he found the plague bacillus in a flea from a living sick rat from an infected house. In the case of 2 out of 9 rats brought in, the flea found on them was *P. serraticeps* (the ordinary dog and cat flea), and in 7 *P. fasciatus*. Manson is reported as having stated, on what authority is not clear, that the fleas of the rat, like those of dogs and fowls, will attack man if driven from their own host. The weak points of the following fresh case of infection supposed to be due to rat-handling are,

that no evidence is offered that there were fleas on the rat or that the rat had died of plague, and that the incubation time seems too short, though the situation of the bubo minimizes this second objection. A daughter of the native head warder of the Yerrowda Reformatory (Poona) died of plague on the 9th October. The family, after segregation, returned to the quarters on the 20th, these having been disinfected and whitewashed. Their second child found a rat dead on the evening of the 22nd, carried it for a minute or two in her right hand, and then threw it away. She developed plague on the 23rd, and died on the 29th, the bubo being in the right axilla. Holub has been experimenting successfully on the use of living insects as a culture medium, but so far he has only used the microbe of soft chancre. The continued experiments in Europe and India (Hankin) on the use of Danysz' bacillus for the extermination of rats do not promise the probability of practical usefulness on the large scale. Bronstein claims to have been more successful than his predecessors through the use of alkalinized feeding media, but, though this may secure a larger number of initial infections, it does not make any more certain the desired subsequent spread from animal to animal. The old idea that the ground being defiled with the excrement of plague-sick rats or with the excretions of plague-sick men, the virus enters through abrasions of the bare feet of the habitually unshod natives, and so produces a relative frequency of femoral and inguinal buboes, receives much acceptance still both among Indian medical men and among foreign savants visiting Bombay for purposes of investigation. But in Sydney 73 per cent. of the buboes were in the groin, and, as Ashburton Thompson says, "the inhabitants of Sydney no more go barefoot than do the inhabitants of London"; and this only confirms what was observed in the case of British soldiers at Hongkong. Simond has shown how the frequency of buboes in that region can be reconciled with the flea hypothesis. But in any case it is evident that the barefoot hypothesis can no longer be supported by the fact of the relative frequency of buboes so situated. Kolle, and also Kossel and Overbeck, have confirmed the observations of the Austrian Plague Commission as to the ease with which certain animals can be infected by gentle friction of the uninjured skin. Several cases of infection through injuries have been reported.

Incubation. Serum reaction. Countries affected.—An Arab deadhouse servant observed by Gottschlich injured his left little finger on the 29th May, and on the 3rd June a plague bubo was found in the left axilla. On October 8th, 1900, a warder at the Brisbane General Hospital assisted at two plague post-mortems, on the morning of the 11th he was ill, and on the 12th it was proved by clinical and bacteriological examination that he was suffering from plague. Dr. Hutchins, who reports the case, does not say that the man wounded himself. Klein and Markl both report favourably on the diagnostic value of the serum test.

* The dates of the deaths are not given.

Plague in the Bombay Presidency.—The incidence of plague was very much less in 1900 than in the two previous years. In every circle, except Kurrachee, the attacks and deaths were very much lower than in the previous year. Whether this was due to the waning of the disease, to the less severe measures, to inoculation, to non-registration of plague deaths, or to the numbers of those liable to plague having been reduced by causes such as famine, the Sanitary Commissioner leaves to the future to decide. In the whole Presidency there were 43,064 attacks and 33,196 deaths, or, excluding the city of Bombay, 25,151 attacks and 19,911 deaths; and 587 towns and villages were affected. In 1899 the whole Presidency had had 126,287 attacks and 96,596 deaths, and 2,256 towns and villages affected. The epidemic continued throughout the year, was at its lowest intensity in July, and reached its maximum in October. The districts of Broach, Panch Mahals, Thar and Parkar, Shikarpur, and Jacobabad remained uninfected throughout the year. Most deaths occurred in the city of Bombay, and in the collectorates of Poona, Belgam, Kurrachee, Thana, and Dharwar; and the highest death rates in the city of Bombay, and in the collectorates of Poona, Belgam, Kurrachee, and then Thana, Nasik, Dharwar, and Sholapur. In the Poona collectorate plague occurred in all the talukas, except Junnar: 86 towns and villages were affected, and there were 6,086 atttacks and 5,086 deaths reported. Only in June was the collectorate free from the disease. There was a large and sudden increase in the mortality in August, and the maximum was reached in October. In the Belgam district, as in 1899, the disease was present during the entire year. The maximum was reached in October. Ninety-three towns and villages were affected, and 6,498 attacks and 4,647 deaths were reported. The increase which took place in the Kurrachee district towards the close of 1899, continued in the first months of 1900, and reached its maximum in April. The disease ceased in June, and the district was then free till the close of the year. In the whole collectorate 16 towns and villages were affected, and 3,164 attacks and 2,446 deaths were reported. The Kurrachee town circle suffered most. Thana district was affected during the whole year, as in 1889. The plague in 51 towns and villages amounted to 2,402 attacks and 2,046 deaths. The maximum was reached in April and there was a secondary increase in August and September.

Plague in the City and Port of Bombay.—As in 1899, plague was prevalent in the city of Bombay throughout the year. The Municipal Commissioner, writing of the period ending 31st May, 1900, says that experience has thrown no new light upon the ways of plague. He quotes various district officers to the effect that the disease is one of localities rather than of particular classes of people; that it appeared to be more localized than in previous years; that the disease sticks to certain buildings with great persistency; that instances occurred where attention to sanitation appeared to confer immunity; that as a rule once a house has been thoroughly disinfected, plague does not visit it again that year, though it is almost certain to do so during the next epidemic. During the year 59 persons affected with plague were not permitted to sail on outgoing vessels; 14 persons on inspection were found to be plague-stricken on vessels and native craft in the harbour, docks, and bandars; and 11 cases occurred in vessels on or before arrival at Bombay from other infected ports, making a total of 84 plague cases in connexion with the harbour. The falling off in the number of cases detected was due to the fact that most of the rejections during 1900 were turned into the town, whereas in previous years they had been kept under observation for some time in a camp. In no instance could plague, breaking out at foreign ports, be traced to the crew or passengers on vessels from Bombay. The known rigorous nature of the examination prevents persons likely to be rejected from presenting themselves.

Plague in Bengal.—The Rajshahi and Chittagong Divisions were entirely, the Dacca, Orissa, and Chutia Nagpur Divisions almost entirely, free from plague, which was severest in Calcutta, Patna, Saran, and Monghyr almost throughout the year, and in Gaya during October to December. The total number of seizures was 40,294, and of deaths 38,412. A feature of the disease, noticed by the Sanitary Commissioner in all places where it prevailed, was that it continued with intense virulence throughout the winter, culminating in March; and that it practically disappeared or remained dormant throughout the hot and rainy seasons, to recrudesce early in October with the advent of the winter. The attitude of the people was always troublesome at first; but after they had been taught by the hard facts of experience, they learned to accept, or even to welcome, the measures instituted for their good. Disinfection of huts, houses, and clothing was largely resorted to in plague-infected areas. As a rule, the result of evacuation, which was sometimes voluntary, was satisfactory; but in some cases the villages were unfortunately reinfected

by the too early return of the villagers, or by the admission of people from other infected villages. The people, however, are said to be learning to guard themselves against these dangers. The district of Patna, which was infected from Calcutta, suffered more than any other, and especially the towns of Patna, Dinapore, Barh, Bihor, and Mokameh. As each village became affected, it acted as a centre for disseminating the disease to its immediate neighbours. Villages situated near main roads were always more likely to be infected early than those more remotely situated ; and in the latter class of villages the disease was nearly always spread by the better class of natives, Rajputs and Babhans. A few cases of gastro-intestinal plague were found. Evacuation of villages showed its best effects when carried out at an early stage, when rats were dying. Towards the end of the year a demand for inoculation arose. In the Gaya district plague was first detected in October in the new town of Gaya. An unusual mortality among rats was soon observed, and the plague bacillus was identified in their blood. Voluntary inoculation was extensively resorted to in Gaya, and became so popular that a whole village asked to be inoculated as soon as plague came near it. In Saran up to the middle of January plague was only known to exist in two circles of the Sudder Subdivision ; but thereafter it was found that a village eight miles east of Chapra was affected, and this proved to be the centre of an extensive spread of the disease. In the Bhagalpur Division the towns of Monghyr and Jamalpur, and several villages were affected. The first outbreak occurred in the villages of Ganga Serai and Jaidpur, near the border of the Patna district, whence the infection was imported. Pneumonic plague was prevalent. An extraordinarily insanitary practice prevailed, the use of large deep pits alongside the houses alternately as grain stores and as receptacles for house sweepings and refuse and for human and animal fæces. Into the town of Monghyr the disease was introduced in March by a Marwari, who had a wedding in his house, to which a large number of Marwaries from Calcutta were invited, with the result that presents of cloth and wearing apparel were brought from the infected localities of that town. Within a few days of the wedding two servants of the Marwari fell victims to plague, and the Marwari himself and his daughter died of the disease. From this centre plague spread very gradually to different parts of the town, by infected people being taken from place to place. It was noticed that mehtars and domes suffered very severely in the town, and women and children far more than men. The civil surgeon reported that many cases occurred of plague breaking out again in disinfected houses, because the disinfectant did not get a proper chance, and was of opinion that the only effective measure is evacuation.

Plague in the City and Port of Calcutta.—The recrudescence of plague in Calcutta in 1900 began in Ward V, and by the end of March it was raging more or less severely in seventeen wards. As in previous years, the wards most seriously affected were generally those in the northern half of the town. The epidemic of 1900, which consisted of 8,822 seizures and reached its culminating point in March, was much more severe than that of the previous year, which had attained its climax in April. Ward V. is composed of bustees of the most filthy condition, and of high masonry buildings divided up by streets of the narrowest possible dimensions, which from their narrowness are useless for ventilation, and are rendered more so by the hanging verandahs on both sides of the streets. The plague authorities of Calcutta have not made up their minds as to the part to be ascribed to rats in the spread of the disease ; but, unlike most other plague authorities, appear to have satisfied themselves that "disinfection is efficacious, while evacuation is unnecessary." Meanwhile the disease has been seriously increasing every year in virulence, and threatens to continue to do so.

No case of plague was found on any of the 462 vessels which arrived during the year from infected ports, and no "infected" ship arrived. Among the crews and passengers of outgoing vessels no case was detected, though it is not known whether some of the rejected persons may not ultimately have developed plague.

Plague in the Punjab.—As far as British districts are concerned, plague in the Punjab was confined to two well-defined areas in the Jullundur and Hoshiarpur districts and in the Gurdaspur and Sialkot districts. During the first half of the year plague was limited to the former of these two areas. This epidemic had begun in October, 1899, and was at its height during the month of March, 1900, though it was severe from February to May. It completely subsided during June, but was followed by another outbreak in October. Early in November a village in the Gurdaspur district was declared to be infected ; and subsequent investigations tended to show that the disease had probably been introduced the previous May by a man who had returned from Bombay and Kurrachee. The disease had remained latent during the hot weather ; but broke out in October, and by the end of the year had attacked six villages in the district and two in the Sialkot district. In

the Punjab 308,048 inoculations were performed, all but a small minority in the Jullundur and Hoshiarpur districts. The only outbreak in the native states dependent on the Punjab was at a village in the Patiala State, situated not very far from the Jullundur-Hoshiarpur infected area, whence, in all probability, the disease was introduced in March.

Plague in the North-Western Provinces and Oudh.—Out of a total of 170 cases with 135 deaths, 145 cases with 115 were recorded in the Mau Aima circle in 1900. Elsewhere 25 cases occurred, of which 20 were imported. The Cawnpore district had six, and the Mirzapore district five ; and cases occurred also at Benares, Agra, etc. The village of Mau Aima in the Allahabad district contains about 6,000 inhabitants, mostly Muhamadans, including about 1,500 *julahas* (weavers). Plague was introduced by a *julaha*, who, with his son and daughter, arrived from Bombay city on the 24th November, 1899. Some of the inhabitants left the village at the first alarm, and went to other villages, and there was the further danger that at that time a large number of *julahas* were returning to the neighbourhood from Bombay, having been thrown out of work by restrictions of employment in the Bombay cotton mills. The Lieutenant-Governor therefore ordered that a large tract of country in the Allahabad and Pertabgarh districts should be brought under a system of inspection similar to that previously established at Hardwar and in some of the eastern districts. On the 17th and 24th January more cases occurred outside the evacuated area at Mau Aima, and it was resolved that the entire village should be evacuated. This was effected by the 2nd February, and the actually infected houses and those adjacent to them were burnt. Similar measures were carried out in three neighbouring villages, which had become infected. The result was quite successful, and all four villages were re-occupied in May and June.

Plague in the Central Provinces.—In the Central Provinces in 1900 there were 634 cases and 590 deaths from plague, of which 627 cases and 585 deaths occurred in the Nagpur district and 527 cases and 493 deaths in Nagpur city. All the deaths among indigenous cases occurred in the Nagpur district. The Nagpur plague of 1900 was a continuation of the second outbreak of 1899, which began in August of that year. The plague in Nagpur city was pretty generally diffused over the city, but was most severe in the Itwari quarter, especially in circles 14 and 15, which are the most densely crowded and dirtiest parts of the city. Five plague villages in the district were infected from Nagpur city, one in 1899 and the others in 1900. In the case of the latter, thanks to the prompt and adequate measures adopted by the authorities, the disease was soon stamped out. The districts of Wardha, Nimar, and Bhandara had only seven cases and five deaths between them, and none of them were indigenous

Plague in Mysore, in the Madras Presidency, and in Madras City.—The epidemic in Mysore was very widespread, no district escaping altogether, though Hassan, Chitaldroog and Kadur had only a few cases each.

The Madras Presidency as a whole was not affected, the indigenous cases throughout the year having been confined to the Salem district, chiefly to the Hosur taluk, which is in immediate juxtaposition to Mysore, a result only attained by great efforts and unceasing watchfulness. The plague followed a very similar course to that taken by it in the preceding year. The severe outbreak in Tiruppatur, alluded to in last year's report, was almost exactly duplicated in regard to point of time, insidious and unrecognized onset, gradual spread, etc., in the neighbouring town of Vaniyambadi, inhabited by Muhamadans of a very ignorant and obstructive race. The relationship between plague and temperature was as clearly marked as usual. No fewer than 57 cases were imported to Bellary, Ganjam, Chingleput, North Arcot, Vizagapatam, Madras, South Canara, Nilgiris, Tinnevelly, Anantapur, Trichinopoly, and Malabar ; but in none of them did the disease obtain a foothold

Plague in Hyderabad State.—Plague was at its maximum in Lingsugur in January, rose again in March, but after September completely disappeared from the district. The disease subsided still more rapidly in Naldurg, and by April had become extinct in that zilla. There were small outbreaks in the districts of Bidar, Gulbargah, and Aurangabad, but they were of short duration, and easily stamped out. The dominions were free from plague from the 16th September to the 24th October. The disease was, however, imported from Nasik into Begumpura, a suburb of Aurangabad city, on the 25th October by a Brahman clerk, who had contracted it from his mother in Nasik. This outbreak in Aurangabad reached its greatest height in the last week in December ; but, as it had been discovered at an early period in its development and promptly combated, it never attained the dimensions of a serious epidemic, and did not spread beyond the suburbs or invade

other districts. This result is said to have been due to the kiln method of disinfection, and to the detention of all suspicious passengers at the three observation camps. In all there were in the Hyderabad State 771 attacks. The total number inoculated in the dominions was 634.

Plague in Rajputana, Berar, Burma, and Baluchistan.—None of the 12 cases recorded in Rajputana were indigenous : they were all imported from plague-infected areas, and detected by the inspecting officials at the railway stations. There were two fatal imported cases, one suspected and the other undoubted, at Khamgaon in Berar, the former coming from the Bombay direction, the latter from Rajputana. Four cases were imported into Burma from Calcutta by sea, two of which at least were undoubtedly plague. In one case the disease did not manifest itself for six days after the infected area had been left. In Baluchistan two fatal cases occurred at Naka Khari in Las Bela State. The two men were travellers by road from Kurrachee to Son-Miani, and had contracted the disease at Kurrachee.

Fevers.

The fever mortality ratio of India increased by nearly 19 per cent., and was nearly 11·5 per cent. above the quinquennial ratio ; the number of deaths rising from 4,126,384 to 4,919,591. The increase affected all the months of the year, but was especially great in the last four. The heading "fevers" includes, of course, many cases for which a more definite diagnosis might be desired, and Garvie has shown reason for believing that many cases of influenzal pneumonia are so included ; but the experience of the other classes of the population already related shows that there was a decided increase of malaria during the year. With reference to the remarks recorded on page 196 of the report for 1898, it is interesting to note that Celli states that the waters in which hemp, and to a certain extent those in which flax, is macerated, during, and some time after the maceration, kill the anopheles larvæ. In Burma the steady and progressive increase in the number of packets of quinine issued to vendors for disposal goes to show that the drug is slowly gaining popularity with the people. In Assam fevers were less prevalent than usual, and this is believed to be the reason why the sales of quinine fell off. The total given for fevers includes 9,036 deaths from *kala asar*, nearly all of which occurred in the districts of Goalpara, Kamrup, Darrang, and Nowgong. But lately portions of the Sylhet district have become affected. In Bengal the year was an unhealthy one, and this was thought to be connected with the deficient and irregularly distributed rainfall. The greatest number of deaths occurred, as usual, in the period following the cessation of the rains. A special report was submitted to Government on the growing unhealthiness of Faridpur, which is supposed to be due to the silting up of the rivers, and to be aggravated by certain local causes. It is said that in Bengal the proportion of deaths returned as from fever is diminishing owing to more skilled diagnosis. The largest sales of quinine corresponded generally with the period of highest mortality from fever. In the Port of Calcutta there were 6* deaths from enteric fever among the European seamen, and 61 from fevers in the native floating population. The Sanitary Commissioner of the North-Western Provinces and Oudh fears that, even with the best system of drainage, the inhabitants of irrigated districts must expect to pay for their abundant crops and independence of rainfall by a somewhat higher death-rate from malarial fever, especially in a wet year. Quinine was sold in the post offices of every district ; it was sold by vaccinators in the majority of districts ; and the experiment of selling it through landlords or their agents seems likely to be successful. A great rise in the fever mortality of the Punjab took place in September in consequence of the heavy rainfall in that month. In certain districts quinine was freely and gratuitously distributed by vaccinators, zaildars, lumbardars, and the medical staff ; and the Sanitary Commissioner recommends the further development of the arrangement. In the Central Provinces the fever appeared to be of the ordinary malarial type ; but there was reason to suspect that deaths from acute dysentery and diarrhœa and other diseases were included. No cases of "famine" or relapsing fever were observed by or reported to the Sanitary Commissioner. The increase of fever in Berar was general in all the districts. Owing to the drought, fevers were not very prevalent in the beginning of the year. Afterwards influenza became prevalent, then simple continued fever ; but, after the rains began, the malarial type prevailed. All these were registered under the head of "fevers." Hepatic complications with symptoms of

* 17 out of 22 cases were admitted from one steamer from a South African port. In the filters were found "organisms which resembled those of enteric fever," and in the firemen's water "an organism which appeared to belong to the higher grades of the coli group."

jaundice were common, not only among the general population, but also in the jails, and in the Hyderabad Contingent. The low death-rates in certain towns of Madras are believed to have been due to a large proportion of the deaths from fevers in these plague-infected localities having been registered under "other causes" to avoid the inquiry as to the cause of death consequent on a report of "fever." In Bombay the number of deaths registered was the highest for ten years past. In some of the districts the increase was to a great extent due to famine causes. A sharp watch was maintained for relapsing fever in the famine tracts, but expert bacteriological research failed to detect it. In two districts an anomalous statistical result was the means of showing that cases of cholera during an epidemic had been returned as "fever."

* Excluding Zamindaries.

Dysentery and diarrhœa.—The mortality ratio for bowel complaints for India rose by more than 111 per cent. and the number of deaths from 252,025 to 530,654. The ratio was also nearly 94 per cent. above the quinquennial ratio. The increase ran through all the months of the year, but was most marked from the beginning of March to the end of September. The high death-rate in the Meiktila district is noted as having been probably due to a contaminated water-supply. The Sanitary Commissioner of Assam cannot understand why the death-rate from acute bowel complaints should always be so much higher in the Sibsagar and Lakhimpur districts than elsewhere, and is causing inquiries to be made. It is stated that in Bengal the increase was chiefly due to causes which contributed to the greater prevalence of cholera; but most of the worst districts have had high mortality for several years past. The mortality was greater in all but four districts. There were 7 deaths among the European seamen of the Port, and 9 in the native floating population. The increase in the Punjab was most marked in the famine districts, especially Hissar. The points of causation noted by the Sanitary Commissioner of the Central Provinces are the failure of the rains in 1899, leading to the use of foul, stagnant, concentrated water from pools; the carrying into the water channels by the rains of 1900 of an unusual accumulation of impurities; the inferior quality of the articles of diet on which the people had to subsist; the ravenous consumption of indigestible vegetables when the rains had set in. The causes cited by the Sanitary Commissioner of Berar are much the same, namely, the consumption of bad jowari and of imported peas to which the people were not accustomed; the want of fresh vegetables during the cold and hot weather, with a scorbutic taint as result; the use of bad water owing to the water-famine;

gorging with green fresh vegetables after the onset of the rains. In Bombay the increase was even greater than in the famine year of 1897. These complaints were most prevalent in Gujarat during and just after the rains, when damp and chills were added to the chief cause—unsuitable food, which consisted of badly cooked or raw grain, grass seeds, leaves, bark, roots, anything that would help to fill the void.

Vaccination.

Vaccination in India as a whole.—The abnormal and untoward conditions which the population of large areas had to face during the year have been the constant subject of remark in the two preceding sections. It might then have been predicted that in the Punjab, the Central Provinces, Berar, Bombay and Ajmer-Merwara there would be a considerable falling-off in the work of vaccination, and a large increase in the prevalence of small-pox, and such indeed has been the case. The contributary causes may be briefly stated; famine and epidemic disease prevailed in these areas; the birth-rate was exceptionally low and the infantile morbidity and mortality exceptionally high; the ordinary avocations of the people were suspended, families were broken up and many of the people wandered far from home in search of work and relief; the vaccinating staff of all grades were largely occupied in carrying out relief and sanitary arrangements and consequently their ordinary functions, inspecting and executive, suffered; and, lastly, the congregation of children at the susceptible age in relief camps where they were brought into contact with destitute refugees from Native States where the protection afforded against the disease is very inadequate, set up conditions favourable to the spread of small-pox.

A decline in the total vaccination operations performed among the civil population of India during the year 1900–01 was therefore inevitable, the aggregate number having fallen from 8,125,337 operations in 1899–1900 to 7,874,392 during the year under

review, yet the result is better than in either of the years 1897–98 and 1898–99, when the totals stood at 7,829,983 and 7,515,527 respectively. Compared with the preceding year, the results of 1900–01 exhibit a decline in Assam, Burma, the Punjab, the Central Provinces, Berar, Bombay, and Ajmer-Merwara; as regards the five latter areas the causes have been sufficiently indicated. In Assam the decrease was insignificant, and to the case of Burma further allusion will be made in the course of this review. Elsewhere, on the other hand, where the above-mentioned untoward conditions were absent or less marked a satisfactory increase in the work has to be noted.

The effect of the presence of plague which has been the subject of remark in previous reports has not altogether disappeared, but it is markedly less as the people are becoming acquainted with the true purpose of preventive operations.

Comparing the year under review with that immediately preceding, the primary vaccinations in the aggregate fell from 7,500,113 to 7,235,020, but the re-vaccinations rose from 625,224 to 639,372, which is evidence on the one hand of the results of the high infantile mortality and the diminished birth-rate, while the increase in re-vaccination was largely due to the greater energy displayed in Bengal, where alone the number rose by about 7,000 cases above that of the previous year. The ratio of success obtained in primary cases was, on the average, 94·5 per cent. against 94·6 per cent. the year before; and for re-vaccinations 64·4 per cent. against 58·7.

As in the previous year, Ajmer-Merwara reported the highest result as regards the percentage of success in primary vaccination, *viz.*, 99·2 per cent., and Madras again takes the lowest place with 89·2 per cent. In re-vaccination the Central Provinces takes the lead with 83·8 per cent., Berar again occupying the last place with 20·9 per cent.

The variation in the result recorded for primary operations is largely due to the use of different kinds of lymph and lymph compounds, which are now on their trial in India, where the conditions vary so greatly in different areas; the range in the success claimed in re-vaccination must, to some extent, be attributed to the differences that prevail in the protection afforded by the primary operation, but much more, it is to be feared, to a lax interpretation of the proper standard of success, a most important matter which is receiving attention.

The foregoing details relate to the combined work of the special staff and of the dispensaries. For the former a total of 7,076,514 primary operations is recorded, 6,700,990 of which (94·7 per cent.) were successful, and 579,274 re-vaccinations, 378,640 of which (65·4 per cent.) were successful.

As to dispensaries no operations were conducted at such institutions in Berar and Ajmer-Merwara. Elsewhere 145,252 primary operations were performed, of which 92·9 per cent. were reported as successful, and only 60,098 re-vaccinations, of which 55·4 per cent. were successful.

With the decline in the total combined operations noted above, only 31·8 per 1,000 of the population can be regarded as having been protected from small-pox, while the year before the estimate stood at 32·86 per 1,000. As the population figures are, however, those of the census of 1891, the figures are necessarily subject to correction, the difference on the aggregate population only amounting, however, to about four per cent.

The average number of operations to the credit of each operator was highest in the Punjab, *viz.*, 2,590, Berar following close with 2,449; Burma next with 2,160. Ajmer-Merwara stands last on the list with 763 operations per vaccinator, due to the decline of work in the province, which was severely affected by famine.

The protection afforded to the infant population is at the rate of 33·9 per cent. of the births calculated on a hypothetical birth-rate of 40 per 1,000 of the population, which is an improvement on the record for the years 1897–98 and 1898–1899, but less than that for 1899–1900, when 38·11 per cent. of the infants were protected on the same computation. The percentages ranged from 55·7 per cent. in the Punjab, to only 12·2 per cent. in Coorg, the lowest returned: the next lowest ratio was 20·7 per cent in Bengal.

The ratio of deaths per thousand of population due to small-pox, which in the calendar years 1898 and 1899 had been 0·26 and 0·23 respectively, rose in 1900 to 0·41; the circumstances leading to this result have been referred to. The increase was most notable in the areas affected by famine, while elsewhere, generally, there was a decrease, *viz.*, in Assam, the North-Western Provinces and Burma.

The total expenditure incurred by the Department in 1900–01 was £77,000 compared with £73,200 in 1899–1900, and each successful case cost 2 annas and 7 pies, against 2 annas and 5 pies in the previous year. The provincial rates ranged from 8 annas and 2 pies in the Bombay Presidency to 1 anna and 4 pies in Bengal.

Total Primary and Re-vaccinations, successful cases among the children, cost of the Special Vaccination Department, during the official year 1900–01.

* For the calendar year 1900.

Animal Vaccination.—As usual, the majority of the vaccination operations conducted in the country were carried out with bovine lymph, either pure or in combination: still humanized lymph is the staple protective medium resorted to in certain areas, notably in the North-Western Provinces and Oudh, though calf-lymph has long been prepared on a small scale in some of the larger towns for local use. But a site for a large central depôt in the Hills near Naini Tal has been selected and plans and estimates for the necessary buildings are under preparation, and it is confidently anticipated that, at no distant date, animal lymph will be available for the entire province, and that the present arm-to-arm system will be gradually superseded. In Bengal, in addition to the vaccine depôts at Calcutta and Darjeeling, one is to be established at Pusa, and the Provincial Sanitary Commissioner advocates another at Orissa. In Burma the Taunggyi vaccine depôt was closed owing to the generally bad quality of the lymph produced there; the entire supply required for the province is to be prepared at the Rangoon depôt, pending the construction of a new depôt at Meiktila or other convenient centre: plans for the building are under preparation, and the plant has been ordered from England. There is no mention in the provincial report of the contemplated central vaccine depôt for the Madras Presidency, but it is known that active steps are being taken in the matter for establishing one in connexion with the Bacteriological Laboratory which is projected.

As regards the several kinds of lymph used, it will be convenient to note the facts when dealing with the work in each provincial area. As already mentioned, the whole important subject of the best form of lymph for use in India is now on its trial. The experiences of recent years have served to bring to notice the rival claims of various calf-lymph compounds, no one appearing, at the present stage of enquiry, to possess exclusive advantages. Owing to various circumstances—differences in climate, and the absence of Deputy Sanitary Commissioners on plague duty, &c.—many questions still await solution, but experiences are being exchanged, comparative tests will be rigidly employed, and the results will be more fully and accurately recorded.

As the main features of this review present some marked departures from the practice followed in previous years, it may be well to indicate here that particulars as regards the work performed by the Dispensary staff as distinguished from that done by the special staff will not be further discussed in the text, as they are given in the above tables. The same remark applies to the average work performed by each vaccinator, to the percentage of available infants protected, and to the cost of the Department in each Province. No allusion has been made to the *personnel* of the staff, as this is now definitely established and has been described again and again in previous reports; moreover, no reference will this year be made to the results (as regards the quality of the work) of the tests applied by the inspecting staff, as, generally speaking, the returns do not distinguish between primary cases and re-vaccinations in this respect. This is a matter in which reform is very desirable, and the necessary orders have been issued to local authorities and the distinction will be observed and reported in future. The following sketch will be confined to a broad statement of the general results of the work, in quantity and quality, together with a brief allusion to the kind of vaccine or compound lymph employed.

Bengal.—Including the dispensary work a total of 2,346,311 operations were performed against 2,252,521 in the preceding year. Of this number 2,227,942 were primary cases and 118,369 re-vaccinations, the corresponding figures for 1899-1900 being 2,203,984 and 48,537, which shows an increase in both classes of work, which is very marked in the latter. The success attending the work was also better, 97·75 per cent. of the primary cases and 59·22 per cent. of the re-vaccinations proving successful, while the year before the rate per cent. was 97·67 and 49·59 respectively.

The aggregate increase of 93,790 operations was not equally distributed all over the province: 31 districts show an increase and 18 districts a decrease on their respective results during the previous year—Mymensingh, which in 1899–1900 reported a great improvement, was at the head of the list in the year under review, with an increase of no less than 16,492 cases.

As regards the districts where a decrease occurred, the causes assigned are generally the presence of plague, the effects of the floods of September, 1900, in inducing widespread prevalence of malaria and cholera.

In response to the Sanitary Commissioner's remarks in last year's report, the protection of infant life in municipalities has received more attention. Deducting the number who died before completing the first year of life from the total number of births recorded in the year, 60 per cent. of the remainder were successfully vaccinated against 44 per cent. in the previous year. This, while a decided improvement, still leaves much to be desired in places where the compulsory Act is in force.

During the year 280,502 primary operations were performed with calf-lymph, 220,347 with lanoline-lymph, and 1,727,093 by the arm-to-arm process. The ratio per cent. of success of these methods and media was 98·46, 94·54 and 98·04 respectively. The quantity of lymph the two depôts at Calcutta and Darjeeling are capable of supplying is said to be insufficient to meet the increased needs, especially as the arm-to-arm system is gradually being superseded, but steps are being taken to relieve the principal depôt of the duty of supplying vaccinated calves and lymph to the Calcutta municipality, which will no doubt go far to meet the difficulty.

The Nepal Darbar and the Sikkim State each received 440 and 2,458 grains of lymph respectively from the Darjeeling depôt ; no record of the results appear to have been received, and as regards the former only it is merely said that they were excellent.

Assam.—The operations during the year numbered altogether 271,466 or 799 less than in 1899–1900, and this represents the work of all the agencies employed.

The primary operations amounted to 251,219 and re-vaccinations to 20,247, while in the preceding year the corresponding figures were 255,131 and 17,134 respectively ; the percentage of success was 95·99 in primary cases and 79·99 in re-vaccinations, results which are lower than in 1899–1900, when 98·50 per cent. of success was claimed for the former and 88·90 for the latter. This decline is apparently due to the inferior quality of the first two supplies of lymph issued at the beginning of the season, a defect which was promptly rectified.

The distribution of the work among the staff shows the paid and licensed vaccinators and apprentices to have performed 240,308 operations, an increase on the 236,031 cases to their credit the previous year, and the dispensary staff only 17,904, or about three-fourths the results of 1899–1900.

The work of the Tea Garden Agency increased from 11,519 to 13,254 : these were exclusively primary cases.

The percentage of success in the primary work was 96·16 for the paid staff, 94·26 for dispensaries and 95·32 for the Gardens Agency : in re-vaccinations the paid and dispensary staffs secured success at the rate of 79·58 and 88·18 per cent. respectively.

The Compulsory Vaccination Act was not further extended and continued in operation in 11 towns, wherein 70 per cent. of the available children under one year of age were vaccinated.

The Vaccine Depôt at Shillong continued to work successfully, and 387,557 tubes were loaded with calf-lymph, which is the highest number on record at the depôt : in 1899–1900 317,382 tubes were filled. The work of the province was entirely performed with this lymph, which in expert hands yielded a percentage of success of over 98 on all cases operated on. The experiments to test the effects of storage on glycerinated lymph, referred to in this report for 1899, were being continued during the year under review.

North-Western Provinces and Oudh.—In the aggregate 1,549,233 operations, an increase of 37,797 on the results of the preceding year, were performed by the special staff in 1900–01, there being 36,522 more primary cases and 1,275 more re-vaccinations, which is a continuation of the progress noted last year. The percentages of success attained were 97·30 and 85·33 as compared with 97·00 and 81·93 in 1899–1900 for primary vaccination and re-vaccination respectively, and thus the steady improvement noticed in the course of the last four years has been maintained. This progress is most satisfactory, especially when it is borne in mind that some of the most experienced vaccinators were deputed to plague and other special duty, and extra caution was necessary in districts where plague prevailed, especially so in the districts of Ballia and Benares.

Vaccination in municipalities declined by 3,381 successful primary operations, and the proportion of persons successfully vaccinated fell to 36·60 per 1,000 of population from 37·97 per 1,000 in the previous year. As stated in the preceding year's report, though the Vaccination Act is in force in all municipalities and cantonments, its provisions are enforced with a varying degree of energy, and here there is certainly room for criticism and improvement.

The humanized lymph supply from the hills with which operations were started was of good quality and received in almost all districts on the plains on due date. Bovine lymph depôts were maintained at Lucknow, Bahraich, and Allahabad, but chiefly for the supply of the lymph to vaccinators working in those localities. Calf lymph is used only to a limited extent at present in the united Provinces, arm-to-arm vaccination being generally practised ; the approaching establishment of a large central lymph depôt has been alluded to, and it is hoped that the present system will gradually be superseded.

Punjab.—The combined efforts of the staff resulted in a total of 782,496 operations, or 160,578 less than in 1899–1900, which latter figure includes 117,163 primary cases and 43,415 re-vaccinations. This decrease is attributed to there having been over 150,000 fewer births in the year compared with the number born in 1899, to the prevalence of famine and scarcity and of epidemic disease, which rendered children unfit for vaccination, to the difficulty in obtaining calves, and to the employment of vaccinators on cholera duty. The percentage of success was 94·44 in primary cases and 63·04 in re-vaccinations, while in the preceding year the results were 94·68 and 62·55 respectively.

No returns for the Native States which maintain their own staff have been furnished in the report for 1900–01, beyond the bare statement that 48,407 primary and 30,377 secondary vaccinations were performed.

The work of inspection is claimed, on the whole, to have been satisfactory, but it was only on the part of the Divisional Inspectors that there was an improvement on the amount of work recorded last year, while the percentage of successful cases to the total inspected was also much the same, save in respect to re-vaccinations inspected by Native Supervisors, who found only 32·16 per cent. successful against 77·59 the year before, a remarkable contrast which is significant of an awakening to an appreciation of a better standard.

The engagement of the Deputy Sanitary Commissioner on plague duties interfered with his vaccination work, and the recrudescence of plague has decided the Local Government to apply for the services of another officer to relieve the Deputy Sanitary Commissioner and set him free for plague duty.

The Punjab Vaccination Notes for the year under review afford no particulars as to the lymph depôt maintained, nor of the yield of vaccine therefrom, but comparative trials of vaseline vaccine and glycerine lymph were instituted on a small scale, the results being inconclusive, and they will therefore be repeated. The great majority of operations are performed with simple calf-lymph, a large and increasing proportion with vaseline lymph, while arm-to-arm vaccination is practised in a small minority. No comparative results are given in the report for the year under review.

Central Provinces.—The total vaccination operations in this Province numbered 437,596 or 46,939 less than in 1899–1900. Of primary cases there were 370,563 against 436,704 in the preceding year, and of re-vaccinations 67,033 against 47,831, that is, a decrease in the former and an increase in the latter. The percentage of success in the primary work was 96·97 and in re-vaccinations 84·73, while in the preceding year the results were 96·50 and 82·73 respectively.

The primary operations in both the British districts and in Feudatory States declined from 354,655 and 82,049 to 303,559 and 67,004 respectively, though the percentage of success was higher, 97·13 per cent. in the former area against 96·65 the year before and 96·23 against 95·82 in the latter area. The number of re-vaccinations however rose from 41,739 to 52,054 in British territory, and from 6,092 to 14,979 in the Native States. The percentage of success in the former was 84·94 against 81·32 in the previous year, and in the latter areas, 84·02 against 92·42 in the year before, results which give rise to grave suspicion.

The explanation of the decline in primary work is the low birth-rate and the heavy infantile mortality, combined with the closure of famine camps, which had in the previous year afforded facilities for vaccinating a large number of children. As regards the increase in re-vaccinations, this is said to be due to the greater attention paid to the matter in consequence of the comments of the Chief Commissioner on the previous year's results, which were not held to be satisfactory.

At dispensaries in addition to the foregoing 17,801 operations, 14,930 primary and 2,871 re-vaccinations, were performed: this is 6,987 less than in 1899–1900. A decrease of over 5,000 primary operations occurred at dispensaries in the British districts, where also re-vaccinations fell to nearly half the number recorded in the previous year. The reasons assigned are that no work was done at two institutions, and that poor-houses and kitchens, where in the preceding year much work had been done, were closed.

As in the previous year four kinds of lymph were used, *viz.*, plain calf-lymph, humanized lymph, glycerine lymph and lanoline lymph, nearly two-thirds of all cases being treated with the first named which yielded success at the rate of 95·6 per cent.: glycerine lymph again gave improved results, the percentage of success being 86·97 against 86·27 in 1899-1900 and 72·69 in 1898-99. The arm-to-arm process by which about 79,000 operations were done, gave successful results in 95·1 per cent., and the 25,000 cases in which lanoline lymph was used yielded, 99·5 per cent. of success.

Berar.—Owing to famine, the prevalence of epidemic disease and the absence of the staff on special duty connected therewith, the total number of operations during the year amounted to only 107,788 against 175,901 in 1899–1900 or a decrease of 68,113, and a decrease of 25,115 compared with the results of 1898–99. Of the total, 74,707 were primary operations and 33,081 re-vaccinations, the corresponding figures in the preceding year having been 120,772 and 55,129 respectively: of the former 96·6 per cent. and of the latter 20·9 per cent. were claimed as successful against 95·8 and 17·2 per cent. respectively in the previous year.

Owing to the famine, calves were not available in sufficient number and lanolinated calf-lymph, manufactured at Amraoti, was used from April to November, thereafter to the end of the working season fresh calf-lymph was employed.

Madras.—The total vaccination operations performed during the year in this Presidency numbered 1,245,719, an increase of 97,899 operations on the results of 1899–1900, of which 84,502 were primary cases and 13,397 re-vaccinations. The percentage of success in the former was practically the same as in the preceding year, *i.e.*, 91·9 and 91·8 respectively, while for re-vaccinations it rose from 76·2 to 77·3 per cent.

The total work done in municipalities increased by about 11,000 operations, and though there was an improvement in the district totals as a whole, yet in six districts there was a decline during the year. Various causes are assigned for this, the chief of which is the absence of members of the vaccination staff without substitutes, on census and other special duty: the lymph supply is also complained of as ineffective in certain places, and attention has been drawn to this.

On the whole the improvement noted last year is maintained, and the plague inoculation scare seems to have entirely disappeared.

As in previous years, four kinds of lymph were used to the following extent, with the results noted against each :—

—	Number of cases.	Percentage of success.
Fresh calf-lymph	210,960	98·8
Ditto in tubes and plates	70,045	94·8
Glycerinated lymph	404,232	91·5
Lanoline ,, ...	383.485	79·1 to 93·4

As usual fresh calf-lymph yielded the best results, and those from gylcerinated lymph show a steady improvement year by year. The locally prepared lanoline paste yielded success at the rate of only 79·1 per cent. in local fund areas, but it rose to 88·5 per cent. in municipalities, while the paste obtained from Bangalore yielded 93·4 and 92·3 per cent. of successful cases in the two different areas named respectively.

The projected establishment of a central lymph depôt for the Presidency has been alluded to.

Coorg.—The total work of the staff in this small province consisted of 11,380 operations, an increase on the number for 1899–1900, which was 9,996. Of the total 9,618 were primary cases and 1,762 re-vaccinations ; one-half of the primary cases were performed among children above one and under six years of age, an indication of the risk to which infants are subjected and which is a feature of other provincial reports ; the percentage of success secured in the two classes of work was 93·89 and 77·01 respectively, while in the previous year the corresponding figures were 94·93 and 76·48.

It is satisfactory to note that the recovery noticed in this report for 1899, from the effects of the plague inoculation scare, has been maintained.

The entire work done in the province was as usual effected exclusively with unmixed calf-lymph.

Bombay.—The total number of operations performed throughout the Presidency was 661,001, which is a decrease of 108,266 compared with the work of 1899-1900, of which latter number 92,917 were primary cases and 15,349 re-vaccinations. This is attributed

to the wide-spread famine and to the epidemic disease which lowered the birth-rate and raised the infantile mortality-rate and set up other adverse conditions to which allusion has already been made.

Of the number primarily vaccinated 532,845 or 90·86 per cent. of the cases were successful, the results in no less than 47,603 cases being unknown, while in re-vaccinations 42,062 or 56·96 per cent. succeeded : here also the results of 23,246 cases could not be ascertained chiefly owing to wandering life led by the people under the stress of famine and pestilence.

In the Native States also the primary cases fell from 185,162, the number recorded in the previous year, to 133,720, and the percentage of success from 95·76 to 92·66. But re-vaccinations rose from 7,116 to 9,756, the percentage of success being 65·76 against 70·04 in the preceding year.

Calf and humanized lymph were used during the year, but the relative results obtained are not stated ; it is intended in future to present a detailed statement of all the kinds of lymph employed, the extent of their use and relative results. Glycerine lymph was tried in Bombay City with encouraging results.

Burma.—The total number of operations performed was 80,426 less than in 1899–1900, *i.e.*, 410,461 against 490,887. The decrease was generally distributed, occurring as it did in 29 of the 38 districts, and is attributed to closer supervision of work and to the severe penalties imposed on the staff for bad work and for falsifying returns.

The details given in the report scarcely bear out the former reason, for Civil Surgeons are said to have inspected only 21·55 per cent. of the total operations and Native Superintendents only 14·92 per cent., against 22·91 and 14·13 per cent. respectively in the previous year, when a larger amount of work was performed. The number of primary operations fell off by 71,110, and re-vaccinations to the extent of 9,316, the percentage of success claimed for the former being 91·69 and for the latter 50·26, against 94·71 and 58·72 respectively in the previous year.

If these results indicate a better standard of work on account of stricter supervision, they are not to be regretted, the higher figures of previous years having apparently been inflated by false returns on the part of vaccinators. The working of the Burma Vaccination Law Amendment Act (Burma Act II of 1900) is not alluded to, and it is not clear if it was brought into operation during the year.

The work of the Department in Rangoon continues to be far from satisfactory. Only 2,265 primary operations and 2,677 re-vaccinations having been performed : returns which are even lower than last year, which were the lowest during the preceding quinquennium. A number of causes conduce to these poor results, the chief of which are the inadequacy of the staff, and of supervision. The total number of births recorded in Rangoon during 1900 was 3,143 and 1,186 infants died within the first year of life, leaving at the least 1,957 to be protected, whereas only 1,046 successful operations were performed on infants below the age of one year. The compulsory Act is in force, but is not enforced and the local municipal authorities are clearly responsible.

The lymph supply from the Taunggyi depôt proved to be generally defective, and this was attributed to prolonged storage before use and to exposure in transit to the site of the operations. The depôt was closed and the staff transferred to Rangoon, which will supply the entire province with lymph until buildings are erected for the proposed new depôt at Meiktila or other convenient station.

Lymph manufactured at the Rangoon depôt was issued in sufficient quantity for 60,000 operations, in compressible leaden capsules and glass capillary tubes, with satisfactory results.

The practice of inoculation is carried on throughout the province and unfortunately the sympathies of the people are in favour of it and against the legitimate operation. The local authorities have, however, not deemed it advisable to take steps to suppress inoculation by legal process, it being thought desirable, in the present stage of public opinion, to depend on vaccination to produce the desired effect on public opinion which in Burma is very backward in its appreciation of sanitary measures. The position in Burma, as regards small-pox and its prevention, would provide an excellent object lesson for the anti-vaccinator, the average death-rate from the disease during the past decade is 0·59 per 1,000 or just 50 per cent. higher than in India, and yet registration is very much more defective in Burma.

Ajmer-Merwara.—The staff performed a total of 10,681 operations, a very large decrease compared with the 27,080 operations recorded in 1899–1900. Of the number, 10,660 were primary cases and only 21 re-vaccinations, against 26,077 and 1,003 respectively in the previous year. The percentage of success secured in the primary work was slightly higher than the preceding year, *viz.*, 99·20 against 99·08, but in re-vaccinations it fell off, from 90·83 to 61·90 per cent.

As only advance statements giving the bare figures have been furnished, it is only possible to conjecture the causes which brought about this great reduction in the work of the Department. Famine and epidemic disease prevailed and militated against the work in the several ways to which allusion has already been made.

Civil Sanitary Works.

Bengal.—Two municipalities were added to the list in Bengal during 1899-1900, the number now standing at 153, excluding Calcutta, and their total income amounted to £312,306, of which 44·93 per cent. was spent on sanitary works (original and recurring), 11·38 per cent. on roads, and 30·8 per cent. on other requirements, the corresponding figures of the previous year being 44·75, 9·97, and 33·8 per cent., respectively.

Under ordinary sanitation charges nearly eleven lakhs were spent on conservancy, nearly 2½ lakhs on water-supply, and nearly 1⅓ lakhs on drainage, showing an advance under each head over the figures of 1898–99, the most notable increase (£2,600) being under water-supply, which was due chiefly to the extension of the filtered supply to new areas in Howrah and to special repairs to the pipe line in Darjeeling. An increase of nearly one lakh under other sanitary works is due to the large expenditure incurred in plague preventive measures. On original works only ten municipalities, or the same number as in the previous year, spent over 10 per cent. of income, 20 against 17 spent between 5 and 10 per cent. and 55 against 48 between 1 and 5 per cent., while 48 against 54 spent nothing on this account; the last number includes many important communities, and the fact calls forth a renewed protest from the Sanitary Commissioner against the lack of enterprise and public spirit displayed by these local bodies.

The total cost of various new works carried out by municipalities and District Boards, by Government and by private individuals, either completed or in progress, amounted in towns to £27,686 against £20,518 in the previous year, and in rural areas, to £33,131 against £36,626; a list of the more important of these undertakings, chiefly "tanks" and hospitals, is given but need not be detailed here.

The Sanitary Board held three meetings during the year, and business was also largely conducted by the circulation of papers to members. Among the more important subjects discussed were the improvement of the Darjeeling water-supply and the health conditions of the Hooghly riparian municipalities. The more important preliminary estimates prepared were those for the Patna waterworks and a combined scheme for the water-supply to the riparian municipalities.

Plans and estimates were considered, and an opinion given, on eleven important waterworks and drainage schemes, details of which are furnished and exhibit the valuable functions performed by the Board in its consulting capacity, which was also exercised in disposing of numerous miscellaneous references made by Government and by local authorities. The Sanitary Engineer inspected critically the waterworks in eight towns, and, in addition, visited several others in his consulting capacity for various purposes.

A useful report on the results of the sewage purification experiments conducted by the same officer at the Presidency jail was issued and distributed to the authorities of the larger municipalities.

Assam.—The total income of municipalities and local bodies during the fiscal year was £16,282 as compared with £18,395 in 1898–99; deducting the amount spent on "roads and bridges," the amount spent directly on sanitation was 44·69 per cent. of income, against 42·74 per cent. in the previous year.

Under conservancy £4,520 was spent against £5,302 in 1898–99; under drainage £713 against £827; and under water-supply £1,447 against £1,725. The proportion of income spent by local bodies on sanitary works ranged from 70·43 per cent. in the Habiganj Union to 18·8 per cent. in the Jorhat Union. A list is given of the various sanitary improvements effected by Local Boards in rural areas, chiefly in connexion with the extension and conservancy of the sources of water-supply, sinking of wells, excavation of "tanks," etc.

The Sanitary Board held three meetings during the year, and at other times views were exchanged by the circulation of papers.

North-Western Provinces and Oudh.—No details of the income, nor of the expenditure on sanitary works are furnished by the Sanitary Commissioner of the North-Western Provinces and Oudh in his report for the year under review, beyond the fact that £72,214 were devoted to the general purposes of conservancy, the sum thus spent in the previous year having been £64,751.

The more important sanitary works undertaken during the year included no new departure, but were in development of schemes already commenced, notably extensions of the sewage works at Benares, measures for the prevention of the pollution of the Ganges at the same place, and extensions and re-modelling of the waterworks at Cawnpore, Naini Tal and Mussoorie.

An important scheme for the drainage and sewerage of Cawnpore City was under consideration throughout the year, but any active progress in its realization will fall to be noticed in next year's report.

Along with these, much attention was paid to the improvement in detail of the waterworks in several of the larger cities, whereby the greater purity of the supply will be safeguarded and enormous wastage prevented. Very useful, if partial, works of drainage were either carried out or planned for the towns of Saharanpur, Aligarh and Farrukhabad. The detailed summaries presented by the Sanitary Commissioner and the Sanitary Engineer leave the impression that the local authorities are pursuing a vigorous policy of sanitary reform in the larger urban centres, and that, especially as regards the splendid waterworks that have been inaugurated during the past decade and which bring an excellent drinking supply to about one-third of the total municipal population, every care is devoted to all details of management and to improvement.

The amount of filtered water consumed per head of population where waterworks are in operation may be briefly stated as of interest for comparison with European standards. In Benares it was 12·7 gallons per head per diem ; at Lucknow, 4·1 gallons ; at Cawnpore, 10·5 ; at Agra, 8·2 ; at Allahabad, 9·4 ; at Meerut, 8 ; at Dehra, 6·6 ; at Mussoorie, 5·4 ; and at Naini Tal 9 gallons. It may be added that frequent systematic analysis of the water "showed good results" throughout the year, save only in that supplied to Agra, measures for the protection of which at the intake have since been carried out. It may be added that beyond the attention devoted to sanitary works in towns, rural areas have not been neglected, many improvements of a minor character having been effected as a result of the visits paid and reports made by medical officers in the course of their ordinary duties, and especially in connexion with plague preventive measures.

Seven meetings of the provincial Sanitary Board were held during the year, when projects and estimates amounting to £14,030 for the sanitary improvement of municipalities were considered. Various schemes for the extension and improvement of existing works for water-supply and drainage were considered, while plans for slaughter-houses and markets also received attention. The reports on the working of the Village Sanitation Act (1892) were read, and the Board noticed with satisfaction the increased attention paid to the conservancy of wells and the evidence of general improvement of the sanitary condition of villages to which the Act has been applied.

Punjab.—The aggregate income of all municipal towns in the Punjab for the fiscal year 1899-1900 was £387,238, including the opening balance, against £385,270 in the previous year. Altogether a sum of £88,691 or 22·9 per cent. of income was expended under all heads of sanitary works, a little over 1 per cent. less than in 1898-99, but this includes the expenditure on "roads and bridges" (£16,125), and if this be excluded the percentage falls to 18·7.

Under conservancy £42,724, under drainage £7,312, and under water-supply £19,240 were spent, or about £5,600 less under the second head, and about one lakh more under the last named than in the previous year, no material difference appearing under the first head.

The income derived from the sale of night soil for manure in all municipal towns amounted to £10,812 as compared with £9,521 in 1899 ; it is considered that far more should be realised if proper care were devoted to the subject to which attention is repeatedly directed.

The chief original works undertaken were extensions to the waterworks in Delhi, Simla, and in Fort Dalipgarh in Bannu district ; the water-supply scheme to the civil station of Dharmsala is under consideration. The Chandni Chauk section of the Delhi drainage works was nearly completed. The extension of the sewage works in Simla is in progress, and much was done towards the completion of the drainage scheme for Fazilka in Feroze-

pore. Three separate projects for the improvement of the drainage of Lahore city were practically completed, and similar works in Rawalpindi, Hazro and Abbottabad are in progress, while several other drainage schemes are under consideration.

As regards rural areas, a considerable amount of activity was displayed by most district boards; the village sanitary notebooks are in use in every district, and they are reported to be fulfilling the function for which they were designed. The Sanitary Board has drawn up a new inspection note-book from which much is hoped, and the system of granting monetary rewards to the village in each tahsil which shows most improvement is being developed, while at the same time the chief considerations which should influence a judgment in these awards were discussed and formulated.

There is indeed good evidence for the Sanitary Commissioner's statement that the cause of sanitary reform is generally progressing in the province, and that a greater impetus will now be given to it by the recent appointment of a sanitary engineer.

The Sanitary Board held two meetings during the year, and business was also conducted by the circulation of papers. Their attention was devoted to the measures cited above for the encouragement of improvements in village sanitation and to questions arising out of the vital statistics of certain towns which have been supplied with drainage systems and waterworks, and where, *primâ facie*, improvement in the public health has not been exhibited; but the premises on which this assumption was based were shown to be partial or misleading.

Central Provinces.—The total income of the municipalities in the Central Provinces for the year 1899-1900 was £71,357, or £4,094 more than in the previous year. Of this total it is said that 28·18 per cent. was spent on "original and recurring sanitary works," but details are not given for the separate heads. So far as can be judged this is about 10 per cent. less than in the previous year, and this is scarcely matter for surprise in view of terrible famine through which the province passed, and which must have involved heavy calls on the resources of local bodies.

The chief sanitary works undertaken were in connexion with the extension, maintenance, or completion of the water-supply projects for the following towns, Khandwa, Burhanpur, Harda, Nagpur and Wardha. A considerable extension was effected in the drainage system of Jubbulpore City, and beyond this a long list is given of minor works carried out by the municipalities chiefly in connexion with the improvement, amplification and conservancy of water-supply sources, a question of the gravest and most urgent importance in view of the great drought that prevailed; a good deal of this work was done by famine labour.

As regards rural areas, a summary is given of the notes submitted by Deputy Commissioners on the working of the Village Sanitation Act, which is by no means generally in force, and the results of which, in the year under review, were not so favourable in all cases as might be hoped owing to the prevalence of famine. Progress in this direction must be slow, but with the return of prosperity there is justification for the hope of better things.

The Sanitary Commissioner observes that "owing to the adverse condition of the province no meetings of the Sanitary Board were held during the year. In several districts the work of sanitary reform was, on account of the general distress and consequent paucity of funds, much curtailed, while in some others it was brought to a standstill." However, a good many minor works, chiefly for the improvement of water-supply sources, were carried out under the Board's direction.

Berar.—The estimated income of the municipalities in Berar in 1899-1900 was £19,019, or £904 more than in the previous year. The total expenditure, under all heads, on sanitary measures, was £8,483, or 44·6 per cent. of income, against 48·4 per cent. in the previous year; this decrease, which is shared by each head of expenditure, being attributed to the large extra charges involved in combating famine and epidemic diseases. Outside the municipalities a total sum of £7,194 was expended by district boards chiefly on drainage (£255), water-supply (£4,125) and "domestic cleansing" (£2,794), sums fairly equivalent to those devoted to the same purposes in the previous year excepting that on drainage, which shows a considerable fall.

The District Sanitary Board met once at each headquarter station during the year to take stock of what had been done on the suggestions made by Sanitary Commissioner in his survey notes on the several towns and villages inspected in past years. A large amount of work devolved on the medical and sanitary executive in the supervision and control of famine relief camps, and it was only to be expected that village sanitation should receive less attention than usual.

Madras.—Excluding the Presidency town, the estimated income of the 60 municipal towns in Madras for the first nine months of the fiscal year was £191,537, as compared with £199,841 in the similar period of the previous year. A sum of £116,053 was allotted for all sanitary purposes, and the aggregate actual expenditure up to the end of December, 1900, was £78,490, against £60,904 in the corresponding period of 1899. The relative distribution of these sums in the two years may be seen by a glance at the subjoined statement, which also gives the figures for the city of Madras for comparison :—

Heads of Expenditure.	Sixty Towns. Population=1,720,202.		Madras City. Population=438,375.	
	1899.	1900.	1899.	1900.
	£	£	£	£
Conservancy	32,652	34,987	22,599	1,761
Improvement of village sites	11,632	12,815	4,618	6,537
Water-supply	13,082	27,063	2,818	1,453
Sanitation of fairs	503	455	—	—
Markets and slaughter-houses	969	792	5,022	4,596
Other miscellaneous sanitary works	2,066	2,379	4,656	44,693
Total	60,904	78,491	39,713	59,040
Income	233,208	191,537	96,501	106,183

Very considerable differences will be noticed in the expenditure under water-supply in the 60 towns and under miscellaneous works in the city, which account for the large aggregate increase in each case during the year under review, but the Sanitary Commissioner affords no clue to the cause of the contrasts exhibited. He reports what was said last year that the necessity for retaining a reserve for the emergency of plague, and in certain cases the incurring of increased expenditure on account of threatened or actual invasion has so tied up or crippled the resources of local bodies that these have been unable to undertake any sanitary works of importance.

The actual achievement in this respect and the different works in various stages of consideration are set forth in the report of Sanitary Engineer. The programme for the year embraced schemes for the water-supply of Berhampur, Negapatam, Tiruvannamalai and Calicut, and for the drainage of Madura. The projects for the first and third named towns were worked out, completed, and submitted to Government, and the others are still in various stages of progress. But beyond these, plans and estimates were drawn up for schemes of water-supply to Chidambaram, Tuticorin, Madura (extension), Trichinopoly and Masulipatam, and for the drainage of Ootacamund. The construction of infiltration galleries in connexion with both the Trichinopoly and Cuddapah waterworks was completed during the year. Of the 60 municipalities, 38 have been surveyed for water-supply schemes and 25 for drainage projects, and as regards 12 in the former category, schemes have either been completed or are in active progress, and some 17 more schemes are under consideration or in abeyance ; while as regards drainage four schemes have been completed or are in progress, and in five cases they are still under consideration or in abeyance. The report affords very full and interesting particulars regarding each town or area which comes into the above statement.

The sanitary works carried out by the local (district) boards during the year consisted in sinking and repairing wells, construction and repair of tanks, latrines, markets, slaughter-houses, &c., and the improvement of village sites. The aggregate estimated income of these district boards amounted to £801,338 against £574,323 in the previous year. Of the former sum £42,424 or Rs. 5·2 per cent. was set apart for sanitation purposes, but little more than half of this was actually spent ; in only four districts was the allotment fairly worked up to. Thus in spite of a very large increase in the resources the sum spent was less than that so devoted in the previous two years, but the necessity of retaining resources in hand for possible or actual plague measures has been the cause

of this lack of enterprise. And thus, although the fear of plague has been the beginning of wisdom as regards sanitary effort in many other parts of India, it is to be feared that Madras has lost ground in the general campaign against dirt and disease even if it has succeeded, in large measure, in keeping plague itself at bay.

There are, however, abundant signs that the sanitary executive is fully alive to its duties and responsibilities; 237 reports of sanitary inspections of towns and villages were received during the year from district, medical and sanitary officers, and it is certainly not from lack of the best scientific and practical advice of which the Sanitary Commissioner's report is witness, that local authorities are at any disadvantage.

The Sanitary Board scrutinised and advised on plans, estimates, &c., for works for a very large number of municipalities, district and taluka boards, and type plans for rural hospitals were drawn up and issued.

Coorg.—No particulars of municipal income are given in the advance proof of the report which alone is available at the time of going to press, but it is said that the sum of £18 was expended by the Public Works Department, and £44 by the various municipalities on sanitary works during the year.

It is also stated that the Sanitary Board held four meetings during the year at which plague preventive measures and some minor matters were discussed.

Bombay.—During the year 1900 there were 165 municipalities in the Bombay Presidency, excluding the capital city, with an aggregate population of 2,196,359 souls; the total income, including opening balances, amounted to £459,667, against £368,446 in the previous fiscal year. Of this sum £97,180 was expended under the three chief heads of water-supply, drainage and conservancy, which is about 21 per cent. of income or a little less than the allotment for the previous year. No details are given of the expenditure incurred under "other sanitary works," "markets and slaughter-houses," "town sites," &c., which in the previous year involved an outlay of some $8\frac{1}{2}$ lakhs, but it is presumed that these responsibilities were not neglected.

The entire income of the 23 District Boards, including 205 Taluka Local Boards amounted to £302,862, out of which £21,497 were expended on the three main heads of sanitary works, a sum approximately equal to that so spent in the previous year.

The Village Sanitation Act (1889) has been introduced into 301 villages, or one more than in 1899. It would appear that owing to plague and famine, which has absorbed the attention of district officers, no progress has been made in the establishment of village committees under the Act, and better times must be awaited. The same must be said as to the number of selected villages into which the sanitary inspection note-book has been introduced, though there is evidence of the greater use to which these records have been put.

The more important sanitary works undertaken during the year are alluded to in the report of the Sanitary Board, which opens with the remark that plague and famine pressed hard on the municipalities during the year, though Government gave considerable grants-in-aid for plague expenditure to many of these local bodies.

The waterworks at Sukkur and Hyderabad were supplemented by additions to the machinery, and plans and estimates were prepared for extending the filtering area of the latter works. Plans for the Kaira and Mehmadabad water-supply schemes have been prepared, while that for Poona is now before Government. Of the Yeola works it is reported that they have been at a standstill for over two years, the municipality being unable or unwilling to provide funds.

The water-supply project for the town and cantonments of Belgaum has been transferred to the Madras military authorities for disposal.

The Ahmedabad drainage scheme which was shelved for more than a year has lately been taken up, but the prospect of progress is not good as the Executive Engineer has not time to devote proper attention to it, and a special Sanitary Engineer, who can give his whole time to the work, is considered essential. The great Poona sewage scheme which comprises the bacterial purification of the sewage and the utilization of the effluent for crop-irrigation has now assumed definite, if not altogether final, shape; the plans and estimates have been submitted to Government, but it is said that neither for the sewage nor for the water-supply scheme is there much hope of realization without a liberal loan from the Imperial authorities.

Finally, the Board advert to their previously expressed opinion as to the advisability of their being endowed with executive as well as consultative powers, to enable them to initiate and supervise sanitary works. They also point to the serious drawback to

progress involved in the multifarious duties which occupy Executive Engineers, who have no time to give proper attention to large sanitary works. It must be admitted that these considerations are well worthy of the attention of the authorities.

Burma.—The number of municipal towns, 41, remained the same. Their total income, including opening balances, was £274,178, against £389,576 in the previous year. Altogether 55 per cent. of income was spent on sanitary works; 9 per cent. on drainage, 11 per cent. on water-supply, 14 per cent. on conservancy and 21 per cent. on miscellaneous "other sanitary works"; in the previous year only 34 per cent. was thus expended in the aggregate.

Prome was the only municipal town where anything appreciable was expended on water-supply or drainage. The laying-on of the river water, though unfiltered, has proved of great advantage to the public health, and a system of drainage is in active progress. Schemes for the extension and improvement of the water-supply at Mandalay and Rangoon are under consideration; it is said that the latter, to cost 11 lakhs, is to be taken in hand without further delay.

Various other projects for which surveys and plans have been completed, are under consideration; *e.g.*, an artesian well for Paungdé; water-supply schemes for Moulmein and Meiktila, while the drainage scheme for the latter has been completed.

On rural sanitation a sum of £10,397 was expended from District Cess Funds, 12 per cent of which was on the water-supplies, 28 per cent. on drainage works, 25 per cent. on domestic cleansing, and 35 per cent. on miscellaneous works.

While much actual achievement has not marked the year under review in regard to large sanitary works in either urban or rural areas, there is evidence of awakening on the part of the responsible authorities, and the next few years should see many useful and important projects completed, while the task of educating the backward population of the rural tracts is not being neglected.

Of the Sanitary Board it is said that proposals for its reorganization were submitted to Government during the year, but these proposals are not given in the report.

General Remarks.

The outlook, past and future.—The century which has just closed, and with the last year of which this report deals, has witnessed great progress in the sphere of preventive medicine in India.

The subject is a fascinating one, whether regarded as in great measure the harvest of the work of one man, Parkes, who laid the foundations of the Netley School of Hygiene and whose inspiration has descended upon successive bands of students unto the present day, or, in its larger aspect, as an important contribution to State economics. But a recital of the achievements of the medical services in this country in the control of sickness and mortality among the British and native troops and the jail population, to which classes of the people alone sanitary measures can be adequately applied in the present stage of public opinion, deserves a separate essay for its adequate presentment rather than a concluding paragraph in this report, the authorised limits of which have been reached. A statement of the kind indicated is, however, projected, and will, it is hoped, appear before long in another place. Here, in the fewest words, it may be stated that for the quinquennial period, 1861–65, the average annual ratio per 1,000 of strength of admissions to hospital (all causes) among British troops in India was 1,636·3, while the death-rate was 26·95; whereas for the five years just concluded (1896–1900) the figures are 1,328·6 and 16·52 per 1,000 respectively; in 1899 the admission-rate was 1,148 and the death-rate 12·75, while in 1900 the former rate was 1,143 and the latter 14·62 per 1,000. And this large saving in life, which is equal to a British regiment per annum, has been effected in spite of the changes in the *personnel* from the older long-service men to the younger and less-developed components of the present army, who furnish the largest proportion of sickness and mortality.

Going further back we find it stated on good authority* that the average annual death-rate per 1,000 of European soldiers in India was 84·6 for the period 1800–30, and that it was 56·7 for the period 1831–56, against the present average rate of 16.

* Professor J. Lane Notter, quoted in "Indian Lancet," 16th June, 1896.

The official records of sickness and mortality among the native troops which are immediately available extend over the last 21 years; in the first quinquennium embraced by this period (1879–1883) the average ratio per 1,000 of strength of admissions to hospital (all causes) was 1,336·2, and the average annual death-rate was 23·95, whereas for the period 1896–1900 the ratios are 781·4 and 11·81 respectively, showing an enormous saving in valuable lives and in effectiveness for service; but the comparison is to some extent vitiated by the effects of the Afghan campaign which occurred in the former period, though it is to be noted that the Tirah and other frontier campaigns (1896–98) come into the latter period. In the quinquennium, 1899–93, the annual average admissions ratio was 1,013·3 and the death-rate 13·92. Lastly, as regards the jail population, it will suffice to quote the figures for three periods for which authentic records are available. During the first, extending from 1832–33 to 1854* (about 21 years) the average annual ratio per 1,000 of admissions to hospital (all causes) was 1,230·2, and the death-rate on the same basis was 70·7; next, taking the first and last quinquennial periods of the last 21 years (1879-1900) we find that for the former the ratios are for sickness 1,194·6 and for mortality 48·86, while for the concluding period they are 980·7 and 29·97 per 1,000 respectively. This last period coincides with the widespread prevalence of famine and scarcity and the consequent excess of epidemic disease among the general population, conditions which drove large numbers of the destitute to crime and flooded the jails to overcrowding, by the dregs of the population, who, never robust, were often in the last stages of disease.

The above facts may be better appreciated if stated in tabular form thus, referring to the mortality ratios only:—

Death-rates per 1,000 *of strength.*

—	1800–30.	1831–56.	1861–65.	1869–78.	1896–1900.	1879–83.	1896–1900.	1833–54.	1879–83.	1896–1900.
European troops	84·6	56·7	26·95	19·3	16·52	—	—	—	—	—
Native troops ...	—	—	—	—	—	23·95	11·81	—	—	—
Jail population	—	—	—	—	—	—	—	70·7	48·86	29·97

This record, remarkable as it must be accounted, is but the earnest of further progress, standing as we do at the opening of a new area in the study of the etiology of tropical disease. The new departure evidenced by the establishment of the schools in London and Liverpool, together with the development of the best methods of pathological research at Netley, has been reflected in the general spirit of enquiry that animates the medical services in India more markedly than ever to-day and which affords ample promise that the high traditions of the past will be maintained. These traditions may be to some extent appraised by the fact that during the past century at least 15 officers of the Bengal service have received the high distinction of the fellowship of the Royal Society, the year 1901 being signalised by two such awards. It is true that the ordinary executive duties of medical officers have for the majority been too engrossing or too distracting (from the constant changes due to the exigencies of the service) to permit of the steady concentration of effort which research work demands. This disability the new bacteriological department will largely remove, and while scope and opportunity for the elucidation of the problems of disease will be afforded to the select few best qualified for the work, an impetus will be given to similar efforts throughout the service. Officers know that the official seal of approval has been set upon the work and that there is a career open to them in the special department if their tastes and talents qualify them for it. The record of the past year affords abundant and gratifying evidence of this, as will appear in the subsequent remarks.

When we come to survey the progress made in the amelioration of the health conditions of the general population, we are met by grave difficulties, with the nature of which those who have followed the facts set forth year by year in the section on vital statistics in this volume, will be familiar (see also the remarks on page 69). The registration

* "Indian Annals of Medical Science," October and April, 1856, and the Report on the Sanitary condition of the Madras Jails, 1856.

of vital phenomena is everywhere, but in varying degree, gravely defective, and as it tends to improve, as is undoubtedly and markedly the case, the mere records do not afford much ground for congratulation, for a higher death-rate may not, often does not, connote a greater proportional mortality. In previous sections of this report some of the main outstanding conditions of life of the people have been alluded to, and many of these are beyond the influence of sanitary effort save that which is embodied in precept and example, which is alien to their sympathies and traditions. The gigantic problem of providing a sanitary environment for the masses who dwell in towns and villages which have grown up without regard to sanitary principles, is one which has long exercised the wit and resources of the authorities, and it can truly be said of the effort that "it moves." In the matters of water-supply and conservancy much has been done; we are encroaching steadily and persistently on the realm of dirt, and we are undermining the apathy and ignorance that beget it. Still this is from the outside, and the homes of the people, which have, for the most part, defied our efforts, present conditions that call for reform, especially in the towns, where overcrowding on the site and in individual dwellings, and the absence of due provision for ventilation favour all the factors that go to make an insanitary environment.

The people, while generally scrupulous in the performance of the rites of which the daily life is one long procession, and which are often based on fundamental principles of personal hygiene, have no notion of *public* health, and very little of corporate effort; each man, in this respect, is a law unto himself and provided he escape defilement the law is well observed. Moreover, the large number of natives who have been trained in medicine and in the elements of hygiene exercise very little influence on their fellows; they rarely lose their own inherited prejudices, and consequently fail to proselytise to their merely formal faith. Our efforts in the sphere of clinical medicine and surgery are appreciated and yet, to a large extent, still suspect and only appealed to as a last resource; they appeal to the people as something occult, ultra-rational and capricious, and as exacting no obligation to defer to the doctor's preventive ordinances.

The provisions of any legal code can only be effectually realized in so far as they represent the conscientious convictions of those to whom they apply; they will be null and void in proportion as they are in advance of, or behind, the stage of opinion reached by the majority. The experience of the results of endeavouring to apply reasonable (to our notions) preventive measures in the campaign against the plague is a case in point; the contrast in the attitude of the people in Glasgow and in Bombay is very suggestive of our limitations in this country, and one of the outstanding mysteries of our policy in regard to plague in the eyes of intelligent foreigners is the fact that the epidemic is treated rather as a political emergency than a matter of public health. It is satisfactory to find that many inclined to scoff at this attitude end by appreciating the necessity for it;* but all this is by way of explaining why Municipal and Village Sanitation Acts fall short in practice of the effects they are intended to realize, why even their simple provisions cannot be rigidly enforced, even if we could trust the native agents to whom the duty nominally falls. At the same time much can be achieved by patience and persuasion as in the case of vaccination against small-pox; here the relation of cause and effect is much more simple, direct and obvious, than the relation which dirt and overcrowding bear to plague, for "dirt and overcrowding" are terms which bear a different connotation in the minds of the people to that we attach thereto. Where we can appeal to their reasoning faculties and instincts they follow, as in the matters of vaccination and of the evacuation of plague infected sites; and herein lies the hope for the future, our practical efforts being directed to the extension of education on the one side, and of the sanitary organization on the other and so to the fostering of co-operation, while at the same time we press on with all those general measures of public health that properly belong to the sphere of the State and its local representatives.

Active measures have hitherto necessarily been for the most part of the nature of a compromise with physical conditions already long established, as well as with ingrained prejudices. The native quarters of the larger towns and of the capital cities have grown without regard to hygienic considerations into the similitude of huge irregular honeycombs. The outbreak of plague has brought this state of things home to the authorities of some of the largest cities, and they are now grappling with gigantic schemes involving the provision of more space, which means more light, more air, and a purer soil, in the

* *See* "Ueber einige Beobachtungen während der diesjährigen Pestepidemie in Bombay, von Dr. Martin Hahn; an address before the Berlin Medical Society, 26th June, 1901.

more densely crowded parts of the inhabited sites. The nature of the problem thus presented may be, to some extent, appraised by the case of Calcutta ; at the census of 1891 the density of the population in the town wards was at the rate of 116 per acre, but in 1901, in spite of a natural decrease (excess of births over deaths) during the decade of some 125,000 souls, the large influx of immigrants, estimated at 270,130 persons, has increased the pressure of the population on the inhabited site to the average rate of 145 per acre.* With the growing tendency to industrial development, the steady and rapid growth of town populations must be anticipated and a great responsibility rests upon local authorities to provide for this by the rigorous enforcement of building laws to prevent the gravest evils to the public health, viz., space overcrowding and defective ventilation. With the rapid development of railways and the consequent establishment of new centres of population, the responsibility for preventive measures in this respect is equally great, and in this case the task should not be insuperable. The problem is one which now affects fully one-tenth of the huge population of the Dependency, and this proportion is likely to be rapidly increased in the near future ; and its gravity is enhanced by the consideration that all measures of public health largely depend for their success on its solution.

Meanwhile, as regards the mitigation of the chief cause of sickness and mortality to which this vast population is subject, the future is bright with promise. The idea of banishing malarial fevers entirely from the list of ills in this country is magnificent, and it is impossible at this stage to forecast how nearly that consummation might be achieved if the interest and intelligence of the people could be enlisted in the campaign, but it need scarcely be said that the practical problem is altogether on a different scale to that presented in Italy where the State is taking vigorous action in pursuit of the policy indicated by the new researches. Here indeed it may be said that the harvest is great and the labourers comparatively few, and, for a considerable time, efforts will have to be concentrated on the more populous and enlightened centres, on cantonments, and on the jails and their surroundings. No apprehensions need be entertained for the present of the embarrassing effects of the general success of these efforts on the natural increase of the population, though this aspect of the question has more than a merely speculative and academic interest. The transformation brought about in the Western Doab districts of the North-Western Provinces by large drainage operations has been described and yet malarial fevers have certainly not been banished from this area, and could we look forward to this achievement the contest of man with his environment would doubtless in the long run result in the same issue ; prosperity and a high birth-rate induce overcrowding and the natural check to increase in one or other form of disease. Malarial disease must be said to be the direct cause of at least one-third of the total mortality all over India, and of a far larger proportion of the total morbidity, and if we could anticipate its elimination, the normal natural increase of population, which may be put at an average of 10 per cent. in the decade, would rise to nearly 25 per cent., and this without taking account of the increased fecundity of the people which malarial disease so markedly impairs.

Before proceeding to a brief review of the work accomplished during the year under the inspiration of the new researches, the lesson of the results of large drainage operations may well be emphasized, especially in view of the desirability of extending irrigation works in tracts where the rainfall is scanty and capricious, and at a time when the railway construction programme is being vigorously pursued ; skilful alignment and adequate drainage are inalienable responsibilities accompanying such public works. For, if from any cause, natural (as by floods and the silting up of river beds) or artificial, the ground water level is permanently raised to within a few feet of the surface, and if water-logging of the soil is induced, the evidence is now undeniable of the deleterious effect on the population, the cattle, the soil, and the water-supply ; while, on the other hand, these conditions being established no sanitary works can vie in efficacy with those adopted to reduce the water level. The evidence afforded as to the transformation effected in the Western Doab is only a repetition of similar testimony previously furnished as regards the area irrigated by the Western Jumna canal†. Water is an indispensable servant but an inexorable master in a tropical country.

Progress in the differentiation of Indian fevers.—In last year's report a résumé of the work accomplished on the formidable task of differentiating the various forms of febrile

---

* In many of the wards it is much higher, and in Bombay city the average in 12 of the wards amounts to no less than 458 persons per acre.

† *See* Dyson, Trans. Ind. Med. Congress, Calcutta, 1894.

disease which have long been a reproach to our nosology was given, and that statement may be supplemented by the remark that the evidence since forthcoming has demonstrated the wide distribution of Malta fever, which may be said to have been found wherever carefully looked for; it has been found in the wilds of the Swat Valley, on the Himalayas at a height of over 7,000 feet above sea level, and in the crowded low-lying cities of Bombay and Calcutta. Similarly, Cerebro-spinal Meningitis and Typhoid fever have been found to have a far more general incidence on the natives of, at any rate, the more populous centres than has hitherto been recognized.

In at least one large centre, Bombay, the practical bearing of a careful discrimination between the various fevers is being realised. Systematic efforts are being made, under the direction of the Health Officer, to mark down the specific nature of all the anomalous fevers that have been classed as "remittents." A great deal of valuable work is being carried out in the separate wards of the city by the Divisional Health Officers, and the microscope and the serum sedimentation tube are being enlisted in the cause of preventive medicine by these busy executive officers, with the result of indicating special foci of disease which raise the general death-rates in large wards.

It is to work of this kind at the hands of medical officers of regiments and of jails that we must look for the all-important and pressing obligation of purging our nosology of obsolete and meaningless terms and for obtaining a scientific survey of the field of Indian febrile disease. No case of fever should henceforth be returned without an attempt at accurate diagnosis; the reform of the nomenclature will necessarily follow, and the all-embracing bane "Ague" will disappear from the records; a diagnosis of ague in an untreated case of fever, without the identification of the parasite, must be held to connote incompetence on the part of the responsible medical officer.

Researches on malarial fevers.—And it is chiefly in respect of the various problems connected with the causation and distribution of ordinary malarial fevers that the work of the year demands notice. The arrival of two Commissioners, Drs. Stephens and Christophers, delegated by the Royal Society to pursue researches into this subject, and especially as regards prevalence of "Black-water fever," afforded the Government of India an opportunity of associating with these gentlemen Captain S. P. James, I.M.S., who had already distinguished himself by his observations in Southern India. The main objects of the Commission's work have been the study of the problems of malarial disease as presented in different districts among the general population, and further, an enquiry into the best practical means of reducing and preventing the incidence of the disease on the inhabitants of cantonments and jails, where the conditions are more easily attacked and controlled. Up to the time of going to press with this report, the town of Calcutta, four districts in Lower Bengal, four districts in the "Duars" (Darjeeling-Tarai), the hill station of Kurseong (5,500 feet elevation) and the cantonment of Mian Mir on the Punjab plains have been visited and surveyed from this point of view.* The routine work has comprised the examination of specimens of blood from large numbers of children and adults of the general population; the dissection of a large number of *Anopheles* mosquitos to ascertain the percentage of infection; a study of the various species of *Anopheles* present in different districts, and the investigation of their habits and breeding places; an examination of cases of malaria under treatment in hospitals; and, lastly in Mian Mir, practical experiments in prophylaxis. Premising that true "endemicity" may be determined by the proportion of children and of *Anopheles* found to be infected (the "endemic index"), it has been found that what is true for Africa in regard to the infection of children and the relative non-infection of adults in malarious places, is true for India. The amount of the infection of children is a reliable index of the general prevalence of malaria. The endemic index was found to range from *nil* in Calcutta to 43, 55, and 72 in the "Duars." The Calcutta districts chosen were those in which all the conditions usually associated with the development of malaria were present, including *Anopheles* in abundance. It is remarkable that not one of the 140 children examined had parasites in their blood, and that not one of the 342 *Anopheles* dissected was infected. In the height of the "fever" season (September) 42 more children were examined with the same results—no parasites and no enlarged spleens. The results of the examination of patients in the hospitals were practically the same, and parasites were only found during relapses in two cases of a chronic type. There are indications that such ordinary malarial infection as occurs in Calcutta is derived from outside the city, and that the risk of contracting the usual forms of the disease therein is remote. But the Commissioners are careful to

* These facts are taken from a preliminary report by Captain James, I.M.S.; the reports of the Commissioners will be published by the Royal Society.

distinguish between malarial disease accompanied by parasites in the peripheral blood, and a form where this diagnostic evidence is wanting. The latter appears to be common in Calcutta, and is of grave type which passes into a true malarial cachexia, the main indication presented by a microscopic examination of the blood being a large increase in the mononuclear leucocytes, a fact to which attention has been drawn by a French Army Surgeon in Algeria.

Proceeding from Calcutta, a definitely increasing endemic index was found as the investigation was pursued across the plains to the Terai country at the foot of the hills, until at Nagrakata parasites were found in the blood of 72 per cent. of the children examined. It is suggested that these marked contrasts might be due either to differences in the actual number of *Anopheles* present, or to differences in the species of *Anopheles* in different places. It is certainly demonstrated that the actual number of *Anopheles* present is no criterion of the prevalence of malaria ; in Calcutta they swarm, and there was, it is said, no obvious evidence of malarial infection (parasites in the peripheral circulation), while in the Duars where the endemic index is very high it was often difficult to capture a specimen of *Anopheles*. This brings out the all-important question as to the particular species of *Anopheles*, one or more, to which the reproach attaches. The Commissioners have themselves met with 20 different species in India,* and this cannot be said to exhaust the list, and they conclude that certainly all cannot be regarded as equally implicated ; and as regards *A. Rosii* evidence is detailed that goes far to show that this very prevalent species is hostile to or immune from the parasite.

The question of the value of the symptom of enlarged spleen as an index of the prevalence of malaria was also examined, and it is concluded that only among children is a relation established (and that not definite) between the "spleen rate" and the "parasite rate" ; it is said that the percentage of children with enlarged spleens in any place gives a fair indication for purposes of comparison, and in the absence of blood examinations, of the prevalence of malaria and the liability to infection.

The Commissioners are now pursuing the study of the practical problems of prophylaxis in the cantonment of Mian Mir, one of the most notoriously unhealthy places in India. The breeding places of *Anopheles* are being marked down, and (the soil is dry, sandy, and porous, and not subject to the retention of surface collections of water) these have been traced to irrigation channels, wells, "tanks" and small receptacles (tins, &c.) near dwellings. Six species of *Anopheles*, two of which are newly identified, have been detected in their transition-stages in the environment and in their adult stage in the occupied houses. The problem of exterminating the former in the long irrigation channels is a serious one, but hope is entertained that by cutting the banks to a smooth inclined surface, by the removal of weeds and sheltering inequalities, and so promoting the velocity of the current, a large measure of success will be attained, and experiments are to be made to test this. Among the children in the bazaars, 30 to 50 per cent. of those examined were found to harbour parasites, and the "spleen rate" was from 70 to 90 per cent. We have then in this cantonment the two essential conditions of endemicity, viz., high percentages of children and of *Anopheles* infected with the specific parasite, and it is not therefore surprising that the troops should suffer grievously from malarial disease. Work on the lines indicated will be pursued in other cantonments.

One of the results of the Commission's labours is to demonstrate that Black-water fever is far more prevalent in India than has hitherto been supposed, but details are held over for publication later.

In connexion with the experiences of the Commissioners as regards the prevalance of true malarial fevers in Calcutta, the observations of Captain Rogers, Indian Medical Service, as set forth in the October number of the "Journal of Hygiene," are of interest. Briefly, he exhibits by means of a graphic chart the divergence—the contrast—between the maximum seasonal prevalence of *Anopheles* in "tanks" and of malarial fevers as manifested by the hospital returns, and further he shows that the fever curve always rises with each "break" of a week or more in the monsoon precipitation, and that the specially unhealthy years are those in which such breaks are most frequent, quite irrespective of the total amount of the rainfall. These breaks are effectual in drying up a very large proportion of the smaller pools and so in diminishing the number of larvæ to be found.

The importance of "tanks" (ponds and lakes) as breeding-places of *Anopheles* is emphasized in view of some earlier authoritative pronouncements to the contrary, and the

---

* It may be mentioned that two species, not previously described as occurring in India, were found to be prevalent in the Duars, viz., *A. funestus* and *A. costalis*, the two species which convey malarial infection in tropical Africa.

fact is of practical moment from the enormous numbers and large extent of these tanks in many parts of the country, for it obviously enhances the difficulties in the way of effective measures of prevention. With the exception of this remarkable prevalence of the larvæ in the tanks during the hot weather (season of minimal fever prevalence) the facts set forth show that the seasonal distribution of these mosquitos in small collections of water, pools, drains, &c., and of malarial fevers, respectively, coincides generally, and are in accordance with recent observations in other parts of India. With the knowledge that *A. Rossii* is the most generally prevalent species in Calcutta, and that there is good evidence for absolving it of any part in the harboring and transmission of the parasite the apparent anomaly disclosed in these observations presents less difficulty than would *primâ facie* appear. Captain Rogers has many pertinent suggestions to offer upon the facts disclosed by his enquiry, and his paper is a valuable contribution to the study of the problem of prophylaxis, while incidentally he discloses the enormous difficulties in the way of the successful application of certain methods that elsewhere appear to afford the best hope of success.

Another example of admirable work is the detailed description of a year's experience of the habits of *Anopheles* in Ellichpur, a cantonment in the northern part of the Deccan* by Captain Glen Liston, Indian Medical Service.

This touches an altogether different side of the subject, while not neglecting the more direct and obvious connexion between the seasonable prevalance of the incriminated insect and that of the disease, for, as the author remarks, it is evident that the habits of *Anopheles* vary in different countries and in different parts of the same country, where the area is so vast as that of India.

Following an account of the seasonal incidence of malarial disease among the troops, the cases being verified by blood examinations, we get a description of the breeding-places of *Anopheles* at different seasons of the year, important variations in the distribution of the larvæ being shown to occur under the varying conditions of the environment. This is supplemented by a series of interesting experimental observations on the eggs, larvæ and pupæ, which serve to elucidate the life-history of these different developmental stages and the conditions favourable or inimical thereto. Lastly, a closely detailed description of the several species of *Anopheles* hitherto found in the area surveyed during the year is given, and illustrated by excellent reproductions of photographs taken from water-colour drawings. On the main facts of the epidemiology Captain Liston's observations are in accord with those already fairly established; the maximum fever incidence coincides with the maximum prevalance of *Anophèles*. The breeding-places may be said to altogether disappear in the hot dry weather; the adult insects, however, survive in large numbers in the Deccan climate until the rains set in, and thereafter a new generation spreads over the country, one collection of water after another becoming infected, this being the period of most general human infection.

To complete this sketch of the work now being prosecuted in different parts of India, a brief reference may be made to the labours of Major A. Buchanan, I.M.S., who is in charge of the Central Jail, Nagpur, and who has recently published an elaborate essay on "Malarial fevers and malarial parasites in India," the result of his enthusiastic application to the subject during the past few years. This is a notable contribution to the literature of the subject based on actual daily observations over a prolonged period, and it affords a comprehensive and stimulating record of observations and experiments on the facts and problems as they present themselves to an acute and resourceful worker who is at the same time a skilful clinician. A remarkable note is struck at the outset, in the acknowledgment made by the author of the capable assistance rendered in these researches by several of his Burmese prisoners, whom he trained to the use of the microscope and who soon became expert in detecting and distinguishing the various kinds of parasites. This is a significant episode affording a gratifying prospect of the multiplication of skilled observers which cannot fail to influence in a marked degree the future progress of the task before us. It is difficult, in the space at command, to summarise even the outstanding features of this suggestive book, which throughout bears the impress of honest work and personal experience guided by imaginative insight. Besides a systematic clinical account of the different forms of fever and the associated parasites, which is the first attempt of the kind in India, there are most interesting and suggestive sections devoted to various special practical aspects of the subject: notably an account of the results of experiments on the action of quinine and arsenic in quartan fever

* *See* "Indian Medical Gazette," October and December, 1901.

and to determine the prophylactic dose of quinine in each variety of fever; a summary of the facts showing the relation of the seasonal prevalence of *Anopheles* to the incidence of attacks; experiments exhibiting the protective effects of mosquito curtains; inoculation experiments; researches on the blood-parasites of birds; an exposition of the clinical facts and appearances in what the author designates "Flagella fever," and many other points, which well repay study, and the book is altogher one that no worker on the subject can afford to neglect.

Space does not permit of a notice of several interesting inoculation experiments, notably those conducted by Captain Fearnside, I.M.S., on himself and on a warder in the Rajahmundry Jail, and those carried out by Major Buchanan, I.M.S., at Nagpur, and described in the book to which reference has been made. Nor can we pause to notice the many attempts now being made by health officers and others to pursue the methods of prophylaxis indicated; these efforts are necessarily in the tentative stage, but so far, and especially where carried out in connexion with small communities and institutions, they are giving promise of gratifying success.

It will, it is thought, be seen from the above brief sketch, and from what follows, that active work is being prosecuted in many different directions of the field of malarial research. As the increasing band of workers gets into closer touch with the varied aspects of the subject, the lines along which enquiry may best be directed become more definitely indicated, and it may be useful to briefly summarise some of these, as they bear on the desirable end of obtaining a survey of endemic malarial disease in this country. The work of the Royal Society's Commissioners, alluded to, affords most useful suggestions, and it may be said that workers should endeavour—

I.—(*a*) to determine the "endemic index" (the parasite rate) together with the "spleen-rate" among native children; it would be well to classify the children examined, by age-periods, 0-5, 6-10, 11-15.

(*b*) In connexion with the above, the seasonal variation (of the endemic index), month by month, should be determined.

(*c*) With this, we need to know the distribution of the different species of parasites in place and season; *i.e.*, the percentage of each variety of parasite found in a particular series of blood examinations.

II.—In connexion with I (*a*) it is necessary to determine the local distribution of *Anopheles*, the percentage of each variety found, and the monthly variation in prevalence.

III.—The characters and distribution of the breeding places of each species of *Anopheles* is also a question of the first importance.

Of course the determination of the fact of infection or non-infection of different species of *Anopheles* (*II*) should be effected where possible.

The Nagpur Conference.—It was considered very desirable to hold a conference on the present position of the whole subject, at which active workers and those especially interested could exchange views on some of the practical problems. The proposal, which was originated by Colonel Scott Reid and Major A. Buchanan, I.M.S., received the approval of the Government of India, and medical officers serving in different provinces were encouraged to attend at Nagpur as the most central rendezvous, and where the work, which has long been in progress, affords special facilities for instruction and experiment.

The work engaged in was extremely practical, consisting of a series of lectures on, and demonstrations of, the well-established facts and of the more recent and unconfirmed observations of the experts, while experiments on new lines were also pursued. Altogeter this new and promising departure was characterised by a thoroughly practical spirit and a subordination of paper eloquence, that marks it off from the usual order of congresses, and that cannot fail to leave its mark on the history of the campaign in India, if only on account of the inspiration and instruction carried away by many officers to all parts of the country.

Among those present were some who have devoted themselves entirely to the scientific investigation of the more esoteric, as well as the comprehensive, aspects of the subject in West Africa and in India; others who have studied the parasites more exclusively in their clinicial forms; naturalists to whom the various species of *Anopheles* and their life-history have afforded an interesting field of study; and lastly, those, who as sanitarians, are chiefly interested in the practical questions of prophylaxis. All set to work to demonstrate practically their contributions to the common stock of knowledge with the result that a comprehensive survey of our present position was obtained. To Drs. Stephens and Christophers, especially, the other members of the Conference

acknowledged their indebtedness for the generous way in which they devoted themselves to the demonstration of the more difficult and abstruse phases of the development of the parasite in the definitive host. The daily work in the laboratory was supplemented by a series of lectures of which the following deserve mention: Dr. Stephens on malarial fever without parasites in the peripheral circulation; Dr. Christophers on the relation of the species of *Anopheles* to malarial endemicity; Major Buchanan, I.M.S., on the malarial parasite in human blood, with lantern demonstrations of the different forms of the parasite, of *Anopheles* larvæ and clinical charts; another paper by the same officer on the so-called "Flagella fever," in which he showed that a secondary rise of temperature takes place in malignant Tertian fever, at the time when the crescentic parasites reach maturity, and when the ex-flagellating forms are found in the blood drawn from the patient. Captain Rogers, I.M.S., discussed the diagnostic value of examination of the blood with special reference to the varying proportions of leucocytes in different fevers. Captain Liston, I.M.S., and Mr. Aitken contributed papers on the classification of *Anopheles* and their natural history, while Captain Birdwood presented a lucid summary of the practical indications for prevention applicable to different communities in India, a question which engaged the Conference in an extremely useful discussion during which the most effectual practicable measures were formulated and embodied in resolutions for presentation to Government; and to these we shall allude immediately.

Lastly, some of the immediately pressing problems of the parasitology received attention. It was clearly enunciated that certain species of *Anopheles* may abound where malaria is not endemic, and that it is probable that certain species are not effective hosts to the parasite; moreover, the different species vary much in their life habits, and particularly in their choice of breeding places; all these points raise questions for study, as has been pointed out in a previous paragraph indicating the lines for further enquiry. Again, it was found that while, in the cold weather, the zygotes would not develop beyond a certain stage at the temperature of the air, development progressed to the stage of sporozoites when the infected mosquitos were kept in a higher temperature by means of an incubator. This throws a light on many failures in inoculation experiments, and has an interesting bearing on the seasonal prevalence of the disease.

Practical preventive measures.—In conclusion, a brief reference may be made to the general plan of campaign which we are now in a position to formulate, but which will, necessarily, require modification according to local social and physiographical conditions. It is of course obvious that surface collections of water cannot be abolished or "disinfected" where the population depends solely thereon for its water-supply, though even here much is possible in the way of conservancy by clearing the banks of tanks of weeds, &c., and, again, certain measures may be applied more successfully to a cantonment than to a crowded native city.

What can be done, and ought to be done forthwith, is to carry out test experiments in various places under different conditions, such as, indeed, are now in progress at Mian Mir and other places; there is, at least, no excuse for delay in applying preventive measures in all cantonments, civil stations, jails, &c., where the medical staff and the requisite labour is available.

Educational.—One of the first requirements is to propagate as widely as possible a knowledge of the simple facts of the etiology of malarial disease and of the rational prophylaxis based thereon. Much is being done in this way by the circulation of literature to medical officers, and of pamphlets to all municipal and district board authorities. A clear exposition of the whole case with adequate illustrations has been drawn up for the instruction of medical subordinates and others, at the instance of this office, by Captain James, I.M.S., and the Nagpur Conference has agreed upon the terms of leaflets for the guidance of different local authorities. The propaganda is being disseminated in ever-increasing measure by the precept and example of medical officers in many places. It is not too much to hope that the simple principles may be inculcated along with the elements of hygiene in all educational institutions, and that medical officers will train subordinates in the use of the microscope, and in the detection of the different forms of the parasite and of the effective host.

Sphere of the State and of its local representatives.—Allusion has been made to the enormous benefits of large public drainage works, and to the necessity that these should accompany all irrigation and railway works and public water-supply systems that affect deleteriously the natural ground-water level, and the surface and sub-soil drainage.

The extension of impermeable brick or stone-lined surface drains, with direct house connections, involving the total abolition of waste water catch-pits so common in the basements of dwellings, is an imperative call on the resources of all municipalities and local bodies and cantonment authorities. Such a measure will effect much more than the prevention or diminution of malarial fevers. Legislation must provide against the common practice of making excavations in the soil of the inhabited site for building purposes, brick and pottery and road-making, &c. Stagnant collections of

water in and near the site must, as far as possible, be removed by drainage and levelling up of inequalities in the site. Old disused wells must be covered in, and the area around those in use must be carefully drained to connect with the main drainage system; stand-pipes, where there is a public water-supply, must be similarly treated. The cultivation of rice should be prohibited within a mile of inhabited sites. All these measures are summed up in the obligation on the part of the public authority to prevent, by all means, the stagnation of water upon the surface and within the upper layers of the soil, and to this end the first step is to procure a detailed survey of the site to locate stagnant collections of water and the breeding-places of *Anopheles*, and to secure the best plans for preventive measures. Ordinary measures of surface conservancy, the removal of waste-matters and of excessive wild vegetation must of course receive attention.

Following the precepts and example of Major Ross in West Africa, special efforts may be directed to the conservancy of domestic premises by "mosquito brigades," where the circumstances permit of this.

In hospitals the segregation of the sick and the protection of other patients by the use of mosquito nets is called for; while in some epidemics of the malignant types of fever ("Kala Azar," &c.) larger measures of segregation may have a more extended application. Public institutions, barracks, and European dwellings should be located at a safe distance from native huts, servants' quarters, bazaars, &c. The prevention of overcrowding in the latter is a measure of importance.

The sphere of the prophylactic use of quinine at the instance of public authorities in this country has its limitations. Its value in jails and similar institutions is not now in doubt. Government has been at pains to put the drug at the disposal of the people in the form of five-grain packets, for each of which one pice (one farthing) is charged at the local post-offices. The demand has not been at all commensurate with, though to some extent proportionate to, the prevalence of fever; if the cost were not a bar to its more extended use, there is still a prejudice, steadily decreasing no doubt, against the use of European medicines, and they are generally only resorted to when native "simples" fail. It would be hopeless to expect the majority to take quinine as a preventive, even if pressed freely upon them. There is no sufficiently marked and prolonged season of absence of malarial infections in this country, as a general rule, when a fair prospect would offer itself of extirpating the parasite in the blood of its secondary host. The conditions are altogether different to those presented in comparatively small well-defined areas of infection, where the seasonal incidence is definite and restricted, as in Italy and some tropical islands.

It is, at any rate, a paramount inducement to marshal our forces and attack this particular evil that every step taken will improve the general health conditions of the people: general measures of drainage, and for the prevention of overcrowding on the site, as well as in the dwelling—more space, more light, more air, and a purer soil—are emphatically the cardinal desiderata which sanitarians have always striven for, and our efforts should now be reinforced and inspired by the hope of more immediate results in the diminution of the chief causes of sickness and mortality. In attacking malarial disease we shall at the same time undermine the causes of tubercular disease, of lung diseases generally, and of bowel complaints. The time has certainly arrived when it is incumbent on every local sanitary authority to utilize and develop its resources to this end.

Sewage disposal.—Another direction in which considerable activity has been displayed in India during the past year is in connection with the question of sewage disposal. In this report for 1898 the present methods and the main general conditions of the problem were set forth, and it was hoped that the experiments then referred to would soon have advanced to a position from which interesting and important indications could be derived, though final and definite conclusions could scarcely be anticipated. It is, however, impossible in the space at disposal to give a detailed account of the results of the experiments carried out in different parts of the country, but these prove conclusively that we have in the "biological" methods an important addition to our sanitary and economic resources. It is scarcely necessary to affirm that the terms of the problem vary in important ways from those that present themselves in England, and similarly they vary as regards the circumstances of the different communities to be served in this country. It has always been a cardinal principle of the sanitary authorities in India that, given the proper conditions, no method of disposal, quâ disposal, could vie with that known as the dry earth and "trenching system," often called the Indian system. But however theoretically perfect, the difficulties in the way of its adequate realization are, for the great majority of communities in this country, so great, if not insuperable, that we are bound to reconsider the whole question. That the assertion that the difficulties are often insuperable is not a mere *petitio principii*, that it rests on solid evidence, will be seen from facts recorded in the report referred to (that for 1898, page 272 *et seq.*), and in a paper on the subject contributed to the last number of the "Scientific Memoirs by Medical Officers of the Army of India"; and this first question acquires special importance from the fact that Professor Ramsay, of London, a member of the Royal Commission on sewage disposal, took occasion during his recent visit to India to deprecate publicly any departure from our present methods.

He says "there can be no doubt that the most advantageous method of disposing of sewage is not to mix it with water, but to return it at once to the soil." He points to the absence of water-supply house connections in Bombay, and from the smaller quantity of water to be removed, he infers "that a convenient and profitable dry system is easily possible," owing to the accessibility and abundance of land and to the presence in India of the caste of sweepers. But he is careful to add, "there may be difficulties which I do not know of; . . . all I wish to convey is that the disposal of solid sewage is much more profitable than that of diluted sewage, if it can be managed." To this it must be answered that there *are* difficulties (many of which have been set forth in the publications referred to above), and that beyond this the dictum that the dry system is "more profitable" must be demurred to. What we have to secure is the rapid and complete decomposition and resolution into the original component mineral and gaseous compounds, of dangerous excreta, without danger to the community previous to and during this process, while at the same time we have to utilize these products of decomposition to the fullest advantage. The circumstances under which the dry system has to be carried out in this country do not fulfil these obligations. Moreover, considerations derived from experience in England certainly do not apply at all generally in India, under the entirely different climatic and agricultural conditions. The fairly regular and equably distributed rainfall in the former provides the agriculturist with all the water he needs for the single or, at most, the double, crop he obtains in the year from one piece of land.

Additional water requires sub-soil drains, while in India irrigation is almost everywhere at one or other period of the year absolutely necessary, and owing to the heat and dryness of the atmosphere the water only penetrates a few inches below the surface. The application of dry sewage to dry land and its reduction by irrigation water is a slow and irregular process, even if the means employed of getting the sewage from the houses to the land were devoid of danger. A matured effluent prepared for direct assimilation by vegetable life is a great advance as regards both safety and economy where the land is cropped so frequently; not only is final resolution more rapidly attained, and thereby danger avoided, but the outturn realised in produce is far higher, and the cost of carriage to the ground is less.

Crude night soil must be carefully and laboriously applied, and is for long not in a condition to benefit the land, which must meantime be kept out of cultivation, at any rate as regards most Indian crops; the effluent on the contrary is immediately available and is equably distributed by methods with which the cultivator is familiar.

It has to be noted first that we have to find water for the soil, and often at considerable expense of time, labour, and money; and that, secondly, there is always a certain amount of foul sullage water to be dealt with in every community even under the driest system, and the problem of the disposal of this is not touched on by Professor Ramsay's plan. The fact that the ordinary dilution of excreta in England ranges from 15 or 20 to 40 gallons per head does not imply that this quantity is required for the fermentation and partial resolution of the sewage under artificial biological conditions; successful results have been obtained in India with a dilution of five gallons, and even three gallons, per head. While manure must be accounted necessary for increasing the value of the crop, water is absolutely essential, and it resolves itself into the best time and method of its application, and there can be little doubt that it is best when containing in solution the readily assimilable manurial elements, and less valuable when poured over raw excreta under the influence of a burning sun. Agriculturists in this country are averse from using crude sewage, and demonstration of the value of *poudrette* has failed in most places to banish their prejudices, while the arrangements for the removal and application of excreta to the land are a constant source of danger and of economic loss owing to the ignorance and unreliability of the low-caste staff on which these essential operations depend. The cheapness of labour in this country is a consideration that is apt to carry too much weight; the number of "sweepers" is by no means equal to the demand in the larger centres, and they often control the situation in defiance of all disciplinary efforts, and they exhibit little sense of duty in their degrading task.

Finally, there are two considerations that have an important bearing on the question; in England the crux of the problem is to produce an effluent that can safely be diverted to a stream; there is always, under any process, an effluent to dispose of. In India, on the contrary, we need a manurial effluent that need not attain the arbitrary chemical standard of purity requisite in England as the land is its ultimate destination, where it disappears and is finally purified and disposed of to great advantage, the fluid being a cardinal necessity for cultivation; there is no ultimate effluent, for all is disposed of by crops or by the soil or by evaporation. And, secondly, the one conclusive fact which the

Indian experiments have demonstrated, is the extraordinary manurial value of a biological effluent as compared with crude night soil, while, moreover, its application can be adjusted to the actual needs of the land under treatment and so with a full economical realization of its value.

This is a matter of such importance that no attempt will be made in this place to present a detailed résumé of the evidence while the full and authenticated records are available in the "Notes on Sewage Disposal" * by Mr. James, M. Inst. C.E., and in the report by the Deputy Director of Agriculture, Bombay, on the cropping experiments at Manjri† in connexion with the Poona scheme. It may merely be stated that the actual income derived from the crops raised on about 3½ acres of land irrigated with effluent and attached to the Matunga Asylum, in the former case, has risen during the last two years to £278 and £380 respectively, giving a net profit on capital outlay (for construction of apparatus and preparation of land, but excluding cost of rent of land) of 21·9 and 26·07 per cent. respectively, results which have enabled the Asylum to increase its accommodation and to undertake the entire responsibility of maintaining fifty inmates without a call on the public revenues. At Manjri the financial results are equally remarkable, the profit on one crop, sugar-cane, raised on land irrigated by "biological" effluents, being authoritatively stated to be at the rate of from £44 to £53 per acre, while that from the same crop on land treated with farm-yard manure with castor cake and *poudrette* was only £20 and £32 per acre respectively. As compared with fresh "night-soil," it is said that the results were better from the use of the "biological" effluent.

It is obvious that the financial aspect of drainage and sewerage schemes assumes an altogether different complexion under these circumstances, and the fact has to be noted that in any case there is always the very serious problem of the adequate removal and disposal of enormous quantities of the foulest sullage water, which under present arrangements, for the most part, finds its way into house basements and into the soil on which they are built. This is indeed a problem that claims the urgent attention of all sanitary authorities and is scarcely secondary to that of the adequate removal of excreta.

In this connexion a new departure having very important sanitary and economic significance is to be found in the utilisation of ordinary town drainage (house-sullage) for the irrigation and manuring of land for cultivation which has been carried out at Meerut on the Demonstration Farm at that place. This sullage was simply diverted from the outfall drains outside the town, on to land under ordinary crops, and the cultivators were quick to realize its manifest advantages. The cultivators pay a small fee for the "lifts" which have been set up to raise the effluent to the level of the land for irrigation. The fee was at first 2*s.* 8*d.* for each lift, of which there are 45 in work, and the sum accruing to the Municipality amounts to £180 per annum, the whole of which is clear profit. It has recently been found possible to raise the fee to 8*s.* and 16*s.* per lift without restricting the application of the drainage. Three crops are derived annually from the land, viz., maize, potatoes, and tobacco in rotation, without any other dressing than that afforded by the sullage; this is a most exhausting series, and yet the manurial constituents of this sullage enable it to be maintained. The gross value of all three crops is reported by an agricultural authority to amount to "not less than £27 and probably more than £34 per acre." This land formerly received heavy dressings of *poudrette*, but the sullage is far more economical, and the rents have risen all round, in some cases to double their former assessments, and they now range from about £3 15*s.* to £7 10*s.* per acre.

It only remains to report that the sewage, including the excreta, of certain wards in some of the large towns in Bengal is already being satisfactorily dealt with on the so-called "biological system"; the matter has also advanced beyond the experimental stage in certain institutions, notably in the Matunga Asylum, Bombay, and in the Presidency Jail, Calcutta, reports on which have been published, while some of the results of the Poona experiments have been referred to. Beyond this, experimental installations are under trial in several cantonments, where the scope for their greatest utility is perhaps most undeniable, and in several municipal towns. We have now arrived at a stage when a careful critical and scientific examination of the results attained is necessary, for the conditions met with in this country will doubtless enable us to throw light on many of the problems that still confront the chemist and the bacteriologist in Europe, and it is from all points of view very desirable that Government should now institute an expert enquiry into the Indian results, and their possibilities of application in practice.

† Bombay Government Central Press, 1901

The Pasteur Institute of India.—As noted in last year's Report, this institution was opened for the active discharge of its responsibilities on August 9th, 1900, and the Committee have recently presented their first annual report. During the twelve months the total number of patients treated was 321, of which 146 were Europeans and 175 were natives of India, and it may be said that the benefits of the treatment have appealed with remarkable results to all classes of the population. There were 96 patients from the European army, 25 from the Native army, 50 from among European civilians and 150 from natives in civil life. As to the results, not a single death has occurred among the 146 European patients and there were only three fatalities among the natives, particulars of which are given in an appendix to the report.

Beyond the special anti-rabic inoculations, the Institute staff performed a considerable amount of bacteriological work, largely in connexion with the clinical diagnosis of enteric, malta, cerebro-spinal and malarial fevers, cholera and tubercle ; and beyond this, a considerable amount of pathological research and of ordinary chemical analysis. A large number of officers received instruction in the essentials of bacteriological work. One other important side of its enterprise that is likely to develop largely in the future is the production of protective sera ; as a commencement, one thousand doses of anti-typhoid vaccine were prepared and issued.

Altogether Major D. Semple, R.A.M.C., the able and enthusiastic Director, is to be congratulated on the very successful first year's work which on many sides holds out prospects of great development ; and that the benefits of this institution should be extended is the desire of the Government of India, who have recently placed an officer at the disposal of the Committee to act as Assistant to the Director.

The Prospects of Bacteriological Research.—The policy of Government in consolidating and extending the work of bacteriological research is also elsewhere developing practical results. The Central Research Laboratory has now been sanctioned, and work will, for the present, be commenced at Bombay under the direction of M. Haffkine, C.I.E., who has hitherto conducted the work of the Bombay Plague Research Laboratory. M. Haffkine will be assisted by a staff of officers selected for their approved knowledge of, and achievements in, bacteriological and chemical research, and it is under consideration to transfer the laboratory to some suitable hill site in order to obviate the exhausting conditions of work in the climate of the plains. The work already accomplished in the Bombay Laboratory has not been, by any means, confined to the manufacture of the plague prophylactic, and a note of some of the more important subjects to which research has been devoted during the past year is given in a subsequent paragraph.

It remains to be said that the proposals of the Government of India contemplate the establishment of a laboratory on similar, but somewhat less elaborate, lines in some central station of each Province, which will work to some extent in touch with the central institution, but be specially devoted to the elucidation of the problems of preventive medicine which press for solution within its own immediate environment. There is already an institution in Bombay in the present Plague Research Laboratory ; the North-West Provinces has a small laboratory in Agra under the control of Mr. Hankin, which only needs development and affiliation with the local school of medicine ; the Pasteur Institute is situated at Kasauli in the Punjab, and this will doubtless be supplemented, when circumstances permit, by a bacteriological department in association with the Medical College at Lahore, the capital ; the Madras Government has recently submitted proposals for the establishment of a Bacteriological Institute, to be combined with a central vaccine depôt, in association with the chair of Hygiene at the Medical College. The Bengal Government has still to move in this matter, the present urgent needs of that large province being served by the small laboratory which is under the control of the Sanitary Commissioner with the Government of India, and which is associated with the researches of Dr. Cunningham, F.R.S., I.M.S. (retired). Lastly, mention must be made of the laboratory at Muktesar, under the charge of Dr. Lingard, which is devoted to research in veterinary medicine. All these institutions, together with the newly established command laboratories specially provided for work in the army, are the growth of the last few years, and although they have already more than justified their existence, we can only be said to be now entering on the campaign with ordered and disciplined forces ; and herein lies the promise for the future of an even more remarkable advance in the control of preventible disease than it has been possible to record for the past in the opening sentences of this section. For it is hoped that we shall not only possess active centres of research, but that one of their chief functions will doubtless be the diffusion of a scientific knowledge of hygiene, in connexion, for instance, with the training of the executive

sanitary staff which must be largely extended in future ; and beyond this, each provincial institution should be the scientific laboratory of the sanitary and medical organizations within its sphere.

Records of Scientific Research.—The work of the Bacteriological Department will form the subject of a brief review in this Report, year by year, but in order to render all important advances immediately available to workers all over India (and to some extent in Europe) it has been decided to modify the issue of the "Scientific Memoirs by medical officers of the Army of India," which was originated in 1884 and of which twelve volumes have been published. The proposed issue will be made in a different *format*, each paper being published separately as soon as possible after the work to which it relates is concluded, so that the delay necessitated by a periodic issue will be obviated, and papers on the same or cognate subjects may be subsequently bound up together. It may be added that these "Memoirs" will not be confined to the record of the work done in the bacteriological laboratories, but will include reports of the more notable results of the labours of officers in all departments under the administrative control of the Director-General and Sanitary Commissioner.

The first issues include a paper by Captain Lamb, I.M.S., and Dr. Hanna on the "Standardization of Calmette's Antivenene"; one by Dr. Hanna on "Researches on Leprosy"; three by Captain Lamb, I.M.S., on the "Etiology and Pathology of Scurvy," on "The poison of Russell's viper," and on "The effects of Anti-cholera Inoculation"; and one by Captain Liston, I.M.S., on "The Structural Anatomy of Trypanosomum Evansi"; all the above are records of work carried out in the Plague Research Laboratory, Bombay. An early number will contain the Report by Captain James, I.M.S., on Investigations into the causation of malarial fevers, pursued in collaboration with the Royal Society's Commissioners, to which allusion has been made in the remarks on this subject.

Red Sea Pilgrim Traffic.—A very brief note will this year suffice to record the arrangements by which the pilgrim traffic between India and Mecca was conducted, for no material change has been made in them, and from the point of view of international public health, they were as usual attended by complete success.

Owing to the prevalence of plague, pious Musalmans were again warned to deter the sacred privilege to happier times, but for those who felt bound to go, all ports in India were closed to embarkation save only Chittagong, and this was only open after the intending pilgrims had been kept under observation by the Sanitary Authorities, and after disinfection of their effects. Three ships in all left this port carrying altogether 1,630 pilgrims for the Haj of 1900, and these were in the first place disembarked at the quarantine station in the island of Camaran, for detention and observation prior to their entry into Arabia and the holy places *viâ* the port of Jeddah. It is reported that about 200 more Indian pilgrims arrived at Jeddah by a roundabout route after proceeding to northern Red Sea ports and re-embarking thence, so that the total number of Hajjis credited to this country was 1,821, which is about equal to the number concerned in the pilgrimage of the previous year. Including these, there were altogether 11,155 pilgrims received at Camaran during the season extending from September, 1899, to March, 1900, a number which is about 3,000 less than that accounted for in the previous season. Only seven deaths occurred in the Lazaret, the principal causes of sickness being small-pox, rheumatism, chest diseases, and "ordinary fevers." Plague was reported at Jeddah, and cases occurred there between the 26th April and the 6th July, with a total of 82 fatalities, but it is said by the local authorities to have been introduced by coasting smugglers, or more probably overland from Assyr, where the disease is endemic ; it is certain that no Indian pilgrims were attacked by the disease during the sojourn in Arabia, but it is reported that one case of plague was landed at Aden from a pilgrim ship on the return voyage to India. No case of plague was reported from Mecca itself. There was a remarkable absence of cholera all along the route.

The Indian pilgrims returned at different dates from the end of April, 1900, to late in the year, as accommodation offered ; some 1,807 are thus accounted for, and they proceeded to Bombay, Calcutta, and Karachi, where they arrived without the occurrence of any notable sickness beyond the single case of plague which was landed at Aden, and of which particulars are wanting. The arrangements for the reception of the pilgrims in India were elaborate and carefully carried out ; in Bombay, the passengers from the ship on which the plague case occurred were kept under observation for 10 days, and the baggage and effects of all pilgrims were disinfected before they were allowed to proceed to

their destinations, those living up-country not being allowed to enter the city, but were sent from the ship to the railway and conveyed home at Government expense. At Calcutta, small-pox having broken out on the homeward voyage, the returned pilgrims were vaccinated, and after disinfection of their effects, were despatched by rail under escort to their destinations.

The above report was written, and refers to a period, prior to my assumption of the office of Sanitary Commissioner with the Government of India ; the proofs were passed by the late Surgeon-General Harvey..

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER FOR MADRAS FOR 1900.

(*Lieutenant-Colonel W. G. King, C.I.E., I.M.S.*)

General Population.

The population of the Presidency, according to the census of 1891, was 35,641,828, inclusive of Europeans and Eurasians. The estimated population is 38,805,409. During the year, 351,076 persons emigrated to places beyond this Presidency and 200,114 came into it, thus leaving the population of the Presidency at the end of the year poorer by 150,962 souls. The natural increase of the population for the year under report was 278,482.

It may be of interest to compare the population according to the census of 1901 (*a*) with that of 1891, (*b*) with the figures representing the estimated population, and (*c*) with its natural growth, as ascertained by adding to the census figure of 1891 the excess of births over deaths during the succeeding decade. The results obtained are contrasted in the subjoined table :—

Population as per census of 1891.	Population as per census of 1901.	Estimated population.	Natural growth of population.
35,641,828	38,219,807	38,805,409	38,109,559

As the Superintendent of Census Operations for 1901 remarks that the figures furnished to this office are "only provisional totals and not finally checked results," it is considered inexpedient to enter into further particulars.

Of the total census population stated above, vital statistics were furnished to this office for a population of only 33,045,683. Over 2·5 millions of persons are thus left out of account. These, as explained in last year's report, live chiefly in hill tracts or in zemindaries, places in which it is not possible to enforce any system of registration efficiently. Towards the close of the year under report, registration of vital statistics was made compulsory, under Act III of 1899, in about 400 villages. Beyond this, there has been no change in the system of registration pursued in the Presidency. The Revenue Department has done a good deal towards securing more correct registration in villages, being aided in its efforts in this direction by the District Sanitary Officers and by the Deputy Inspectors of Vaccination. This office has also rendered assistance by carefully scrutinizing the results obtained in each district and town, and drawing the attention of the officers concerned to instances in which there were reasons for regarding the work of registration as untrustworthy. In this connection and during the past year, these officers were addressed on 253 separate occasions.

Births in Districts.—The birth-rate for the year was 31·8, or 0·5 per 1,000 above that of 1899. This is the highest rate on record, as will be seen from the following statement.

Years.	Birth-rate on the census population.*	Birth-rate on the estimated population.*	Years.	Birth-rate on the census population.*	Birth-rate on the estimated population.*
1892	25·1	24·4	1897	25·3	23·0†
1893	26·9	25·9	1898	24·6	22·0†
1894	27·7	26·2	1899	31·3	27·4
1895	28·9	27·1	1900	31·8	27·1
1896	29·1	26·8			

* Inclusive of Europeans and Eurasians both in the births and population.
† Famine influence.

Considered individually, Madras, with a recorded birth-rate of 46·1 per 1,000, takes the lead among the districts and is followed by Chingleput with 40·2. The results obtained in thirteen other districts were also good, the rate registered in them having exceeded 30 per 1,000. In the remaining seven districts, the rate was above 25 per 1,000. This branch of district administration appears to have received more attention than in previous years, as evidenced by the good results achieved. Compared with 1899, it is observed that, with the exception of Anantapur, Bellary, Cuddapah Ganjám, Gódávari, Kistna, Tanjore, and Vizagapatam, all the districts show an improvement. The fall in the birth-rates in Anantapur, Bellary, Cuddapah, and Kistna must be ascribed chiefly to the prevalence of famine in those districts during the year. In the remaining districts it is probably due to a similar cause, viz., the high prices, bordering on famine rates, that were prevalent during the major portion of the year.

Considered with reference to sex, the proportion of male to female births was 104·6 to 100.

Classified according to races, the birth-rates were as follows :—Native Christians 30·7, Muhammadans 32·1, and Hindus 31·8 per 1,000 of their respective populations.

Deaths in Districts.—The deaths recorded during the year under report aggregated 770,859, or 23·4 per 1,000 of the population, as compared with 675,094, or 20·1 per 1,000 in 1899, the increase occurring in all the districts but four, viz., Bellary, Salem, South Canara, and Trichinopoly, and appearing mainly under cholera and fevers.

The following statement compares the death causation in the Presidency for a series of years :—

Years.	Birth-rate per 1,000 of population.	Percentage of deaths from						Death-rate per 1,000 of population.
		Cholera.	Small-pox.	Fevers.	Dysentery and Diarrhœa.	Injuries.	All other causes.	
1892	25·1	10·5	5·8	37·4	4·3	1·5	40·5	22·3
1893	27·0	5·0	4·2	39·9	3·6	1·6	45·7	19·3
1894	27·7	6·3	1·7	40·2	3·7	1·7	46·4	20·0
1895	29·1	3·2	0·8	42·1	3·6	1·6	48·7	19·6
1896	29·9	7·1	1·4	38·6	3·7	1·6	47·6	20·6
1897	28·7	17·3	2·6	35·3	4·7	1·4	38·7	25·4
1898	27·4	9·4	2·9	35·6	4·2	1·6	46·3	21·0
1899	31·3	4·3	2·5	36·4	4·6	2·0	50·2	20·1
1900	31·8	7·8	3·9	39·3	4·1	1·8	43·1	23·4

Excluding Madras, the highest death-rate in the Presidency was returned by the Nilgiris (34·4), followed by Tanjore (30·1). In the former case it appears to have been mainly due to the prevalence of fevers, while in the latter it was owing to the large

mortality registered both under cholera and fevers. As in the previous year, Ganjám returned the lowest death-rate at 16·4 per 1,000.

There was an improvement in 14 and a retrogression in 18 towns. The results prove that registration in these latter is defective and unreliable. From reports received from the collectors it is observed that in 23 out of the 33 towns, with a population of over 10,000, the provisions of Act III of 1899 have since been brought into operation. Better results may therefore be expected in future. Inasmuch as such a measure is calculated to bring about much-needed improvement, I see no reason why the Act should not be extended to the remaining towns.

The increased infantile mortality from 159·0 to 164·9 during the year under review must be set down as mainly due to the high prices of food that ruled during the greater part of the year.

Births in Municipalities.—The birth-rate for the municipal towns in the Presidency averaged 38·5 per 1,000 against 37·0 in 1899. Of the 61 municipal towns, two, viz., Tinnevelly and Vániyambádi, yielded annual birth-rates of 55·5 and 53·7 per 1,000 respectively. In 18 towns the rates obtained ranged between 40 and 50 per 1,000, while in 37 others the rates varied from 30 to 40 per 1,000. There thus remained four towns in which the rates recorded were less than 30 per 1,000. Comparing the year's results with those of 1899, it is observed that there was a decrease in the birth-rate in 25 towns and an increase in 33 towns. The decrease was very marked in Tirupattúr (18·6 per 1,000), Anakápalle (8·4), Adoni (7·4) and Chidambaram (6·8). In the case of the first-mentioned town it was brought about by the outbreak of plague, which scared away a considerable proportion of the population from the town, besides interfering with the work of registration in consequence of the attendant confusion. A reaction appears to have set in in the case of Berhampur, Chicacole, Parlákimedi and Cocanada, which showed signs of improvement last year. The cause of the decline is not apparent, and must be set down to laxity in the performance of the work of registration. It is satisfactory to note the increase in the birth-rate in Karúr, Bezwada, Kurnool, Ootacamund, Tiruvannámalai, Tinnevelly and Trichinopoly. Cuddapah also showed an increase over the previous year, but there is still much room for improvement.

Deaths in Municipalities.—The average municipal death-rate for the Presidency was 34·4 as against 30·7 in 1899, the increase being due, mainly, as in the case of rural areas, to the prevalence of cholera and fevers. As compared with the quinquennial average, there was an increase in the death-rate in 38 municipal towns and a decrease in 20 others. Compared, however, with the results of 1899 there was an increase in 43 towns and a decrease in 17. The increase was largest in Bezwada, Guntúr, Nandyal, Palni, Periyakulam, Palghat, Tinnevelly and Tuticorin, being largely contributed by cholera. In 26 towns there was an increase both under births and deaths which may be regarded as the result of careful supervision. The increased mortality in Madras appears mainly, as is to be expected, under fevers.

The average infantile death-rate for the municipalities was 223·3 for the year under report as against 223·9 in 1899. The falling off, small as it is, is noted with satisfaction, inasmuch as it has occurred in a year when the food-grains were selling very dearly, a circumstance which is inimical to infant life. There was an increase in the infantile death-rate in 31 cases, in 12 of which the increase was over 30 per 1,000.

Chief Diseases.

Cholera.—The total mortality from cholera amounted to 60,662, or 1·8 per 1,000 of the population, as against 29,082, or 0·9 per 1,000 in 1899. An increase is observable in almost all the districts. The number of affected villages was 6,051 as against 3,794 in the previous year. Madura, Tanjore, Tinnevelly and Gódávari suffered most, the death-rates in these districts having ranged between 4·7 and 3·0 per 1,000. As has been pointed out in previous reports, the incidence of mortality from this cause was heaviest in the districts affected by the south-west monsoon in July, August and September, and in those affected by the north-east monsoon in October, November and December.

From 49 out of 61 municipal towns, 5,789 (=2·7 per 1,000 of the total urban population) were reported from cholera, Periyakulam taking the lead with a death-rate of 20 per 1,000, followed by Tinnevelly (13·8) and Palni (12·4) per 1,000. The mortality was also heavy in 14 other towns, in which the rate varied from 10·1 in Tuticorin to 4·2 in Máyavaram. In Madras cholera broke out in an epidemic form about the middle of

last year, and continued till its close. In all, 606 persons died from this cause. In September, 1900, deaths from cholera were reported from certain villages lying in close proximity to the Red Hills tank. Effective measures were promptly adopted to combat the epidemic and thus protect the Madras water-supply from contamination.

Permanganate of potash, as a means of purifying contaminated sources of water-supply, continues to be favourably reported on by medical officers.

Small-pox.—Small-pox accounted for 27,692 deaths, as against 16,991 in 1899. They were reported from 5,891 villages in the Presidency as against 4,177 in 1899. The largest number of deaths occurred in Gódávari (7,298, or 3·5 per 1,000, Tanjore (3,853, or 1·7), South Arcot (2,585, or 1·2), and Madura (1,966, or 1·2). Of the 27,692 deaths reported, 8,249 were under one year and 7,269 under ten years of age, the proportion borne by these figures to the total mortality under this head being 29·6 and 26·0 per cent. respectively. As remarked in previous reports, infantile mortality from this cause cannot be minimized without having recourse to legislation. Until vaccination is made compulsory in rural areas, more satisfactory results cannot be hoped for. Although vaccination is appreciated by the bulk of the population, mothers are still reluctant to submit their children to the operation, being swayed by such considerations as tenderness of age, physical inability to bear the effects of vaccination, &c. During times of small-pox prevalence it is customary for local bodies to detail special vaccinators for work in the affected parts, with the object of reducing the number of the unprotected, but their best efforts are often thwarted by the unwillingness evinced by the people to undergo the operation while the disease is present. The total number of deaths from this cause, reported from the municipal towns in the Presidency was 683, or 0·3 per 1,000, as against 471, or 0·2 per 1,000, in 1899. The death-rate was large in Nandyal (4·2), Rajahmundry (2·3), Coimbatore (1·4), Dindigul (1·2), and Ellore and Vellore (1·1 each). The largest number of deaths reported from any town from this cause was 64. This number was registered in Coimbatore and Rajahmundry. Eighteen towns enjoyed complete immunity from this malady. The rate of mortality from this cause among the rural population was 0·9 per 1,000 against 0·3 in the case of the urban. The contrast afforded by these figures lends support to the demand for making vaccination compulsory throughout the Presidency.

Fevers.—Fevers contributed 288,521 deaths, as against 254,549 in 1899, the increase occurring in almost all the districts. Out of 39,922 villages in the rural areas, 24,367 villages returned deaths from fevers against 21,975 villages in 1899. The death-rate was largest in the Nilgiris (25·2), Vizagapatam (17·6), Cuddapah (15·3), Kurnool (14·7), Kistna (14·4), and Madras (13·3). Compared with the average rate for the five previous years, there was an increase in the death-rate in thirteen districts and a decrease in eight. The deaths were larger in the latter half of the year than in the former half and the greatest number was recorded in the month of December.

From municipal towns, 15,726 deaths were reported from this cause, as against 12,512 in 1899, the increase occurring in thirty-six towns, excluding Madras. The death-rate was largest in Nandyal (16·7), Kurnool (13·4) and Kodaikánal (13·2), and lowest in Vániyambádi (0·3), and Tirupattúr (1·5). These low rates are probably due to a large proportion of the deaths from fevers in these plague-infected localities having been registered under "other causes," to avoid the enquiry as to the cause of death, consequent on a report of "fever."

Dysentery and Diarrhœa.—Dysentery and diarrhœa caused 38,858 deaths, or 1·2 per 1,000, in 7,286 villages against 31,307, or 0·9 per 1,000, in 6,693 villages in 1899. The largest death-rate was recorded in Madras (7·7) and Chingleput (3·3). Compared with 1899, Malabar shows an increase of 1·1 per 1,000, Tinnevelly 0·8 and Ganjám, Madura, Nilgiris and South Canara 0·5 each per 1,000. When compared with the five-year average, it is observed that sixteen districts exhibit an increase. July and August were the months in which the greatest mortality from these diseases occurred. The municipal towns returned a total of 10,364 deaths, or 4·3 per 1,000 from these causes, as against 9,182, or 4·3 per 1,000, in 1899. Compared with the rural death-rate (1·2), the urban (municipal) shows a large increase (4·8). Setting aside the question of insanitary surroundings as determining the rate of mortality from this cause, this variation may be due to the greater accuracy in terminology secured in municipalities, where the agency employed for the registration of vital statistics is better educated and supervised than in rural areas. The death-rate was large in Tuticorin (10·7), Palamcottah (10·2), Chingleput (9·5), Gudiyáttam (9·4), Guntúr (9·4), Vizianagram (8·1), Bezwada (8·1), Palghat (7·9), Madras (7·7), Periyakulam (7·2), Coonoor (7·0), Vizagapatam (6·9), Ongôle (6·6) and

Parlákimedi, (6·0). As already explained in the report for 1899, the large mortality in these towns must be due either to defective conservancy or a contaminated water-supply, or to both.

Injuries.—The deaths registered in 1900 as brought about by injuries aggregated 13,677, or 266 more than in 1899. The death-rate was 0·4 per 1,000 of the population. The largest number of deaths by suicide (1,553) was returned by Gódávari (166), Malabar (135) and Tinnevelly (111). As usual, suicide among females was more frequent than among males. Compared with 1899, there was an increase in the number of deaths from wounds and accidents (from 9,441 to 9,707) and from snake-bites (from 2,036 to 2,217), and a decrease in the killed by wild beasts (from 236 to 200).

All Other Causes.—The deaths registered as due to unspecified causes ("other causes") amounted to 341,449 against 338,754 in 1899, giving a death-rate of 10·4 per 1,000 as against 10·1 in the preceding year. The increase in the death-rate is probably due to the indifference of the village officers in registering death causation, as explained in the report for last year.

Sanitary Works.

Municipalities.—The major works undertaken by the civic corporations, such as water-supply and drainage schemes, are dealt with in the Sanitary Engineer's report, forming Part II of the Sanitary Board's report. The minor works undertaken for execution fell under one or other of the following heads :—

(1) Construction and repair of wells and tanks.

(2) Construction and repair of drains, public latrines, cinerators, dust-bins, markets, slaughter-houses, &c.

(3) Improvement of village-sites, &c.

As has been pointed out in previous reports, the drinking-water supplies and drainage of the majority of the towns are defective to a degree, and until the defects have been remedied for some considerable time, it is useless to hope for evidence of any marked and lasting improvement in the public health.

The total estimated receipts for 1900–1901 amounted to £191,537. About 60·6 per cent. of this income was allotted for expenditure on sanitation. The actual expenditure during the first nine months of the year was 67·6 per cent. of the assignment. In no less than forty-five towns the proportion of the sanitary grant utilized in the period referred to fell below 75 per cent.

The annexed statement shows in detail the expenditure for the year 1899–1900 and for the first nine months in 1900–1901, under each item of sanitation :—

	1899–1900.			1900–1901.		
	Amount sanctioned.	Amount expended.	Rate per cent. of expenditure to total allotment.	Amount sanctioned.	Amount expended during the nine months ending December, 1900.	Rate per cent. of expenditure to total allotment.
	£	£		£	£	
For conservancy	57,595	42,333	73·5	49,689	34,987	70·4
For improvement of village or town sites.	15,751	15,006	95·3	18,401	12,815	69·6
For improvement of water-supply, cleansing, repairing, and construction of tanks and wells.	56,209	22,440	39·9	40,255	27,064	67·7
For sanitary arrangements during fairs and festivals.	2,104	705	33·5	816	455	55·7
For construction and repair of markets and slaughter-houses.	1,233	1,214	98·5	1,680	792	47·1
For other sanitary outlay ...	3,094	2,743	88·6	5,213	2,379	45·6
Total	135,986	84,441	62·1	116,054	78,492	67·6

District Boards.—The long-looked-for Amendment of the District Boards Act has at last been effected and the Act thus revised has come into operation since the 1st of April last (1901).

The sanitary works undertaken and carried out by local boards during the year consisted in the sinking and repairing of wells, construction and repair of tanks, latrines, drains, dust-bins, markets, slaughter-houses, etc., and the improvement of village sites and water-supply generally.

Tanks, wells, ponds, rivers, springs or canals were the sources from whence people obtained their supply of drinking-water. In the majority of cases watchmen were employed to prevent the water from contamination. Side cuttings, chiefly intended to carry off storm water, were the only means whereby the majority of the villages were drained. Out of a total of 39,921 villages, 583 were conserved, as against 640 in 1899. Of these, 380 were union and 203 non-union villages, the corresponding figures for the previous year being 384 and 256. The number of villages conserved was largest in Gódávari and smallest in the Nilgiris and Malabar.

The estimated receipts of the year (1900–1901) amounted to £801,338 against £574,323 in the previous year. Of this sum, £42,424, or 5·3 per cent., was set apart for sanitation. The expenditure during the first nine months of the year was only 57·6 per cent. of the allotment. With the exception of the districts of Ganjám, Gódávari, North Arcot and South Canara, the allotment was not fairly worked up to.

The following statement exhibits the expenditure on sanitation during the year :—

	1899–1900.			1900–1901.		
	Amount sanctioned	Amount expended.	Rate per cent. of expenditure to total allotment.	Amount sanctioned.	Amount expended during the nine months ending December, 1900.	Rate per cent. of expenditure to total allotment.
	£	£		£	£	
For conservancy	22,605	19,874	87·9	21,891	16,681	76·2
For improvement of village or town sites.	4,319	3,482	80·6	4,372	1,386	31·7
For improvement of water-supply, including cleansing, repairing, and construction of tanks and wells.	7,342	5,434	74·0	8,179	3,207	39·2
For sanitary arrangements during fairs and festivals.	1,266	878	69·3	1,224	582	47·5
For construction and repair of markets and slaughter-houses.	3,940	2,820	71·6	4,760	1,973	41·4
For other sanitary outlay	2,004	835	41·7	1,998	617	30·9
Total	41,476	33,323	80·3	42,424	24,446	57·6

Personal Proceedings and General Remarks.

Efforts were continued during the year to increase the efficiency of the registration of births and deaths. Reports of inspection of registers by District Medical and Sanitary officers, when disclosing want of care by the subordinates concerned, were transferred by me, with remarks, to Collectors of districts. Collectors were invited to forward statistics of villages, under the Compulsory Registration Act (Madras Act No. III of 1899), with the object of ascertaining how far this Act met the difficulty, referred to in my preceding reports, of the revenue headmen of villages being saddled with the duty of registration when the population assumes unmanageable dimensions. Municipalities were again addressed as to the necessity for following up failure to register by prosecution. In connection with a reference on the subject of existing arrangements for registration in the City of Madras, my recommendation of 1891 as to the advisability of having a double set of registers in large towns where qualified practitioners exist, so as to secure correct nomenclature in at least a certain percentage of cases, was again submitted to Government. Proposals having for their object the limiting of the influence of the existing form as used in rural areas for registration, in bringing about stereotyped returns of deaths under "all

other causes," have lately been placed before Government. As soon as it was possible, month by month, to collect and review the statistics received from all parts of the Presidency, the attention of each of the authorities concerned was invited to defects discovered in registration. Irrespective of such efforts on the part of this office, reports received from various districts show that increased attention has been bestowed on the subject by District officers.

Allusion has already been made to financial difficulties causing hesitation on the part of municipalities to undertake new sanitary works. Whilst, in the case of these towns, there is some excuse for this state of affairs, the tendency on the part of certain of the Local Fund Bodies to omit to make provision in their budgets for permanent sanitary improvements, under Grant I. cannot be so regarded. I consider it essential that each Local Fund Board be required to show, year by year, that it has carried out some permanently useful sanitary work Nevertheless, 117 separate references for opinions as to plans and estimates for sanitary works have been dealt with from a sanitary point of view by me, on behalf of the Sanitary Board during the year.

The revised District Boards Act, to which I have long looked forward, in the hope that it would secure certain, hitherto impossible, elementary reforms in rural areas, was published during the year and will come into force in April, 1901. It contains several advantageous sanitary rulings that cannot fail to be of utility in such primary matters as protection of water-supply, conservancy, and the combating of infectious diseases. Without, however, the executive machinery for using the legal powers thus gained, no advance can be expected ; yet, although the subject has frequently been pressed upon their notice, Local Boards possess but few Certificated Sanitary Inspectors. Frequent refusals to entertain even the class of men now available as Certificated Sanitary Inspectors, on the ground of "want of funds," has proved to me that it would be hopeless to persuade these Bodies, for the next few years, to entertain the scheme I had advanced in 1899, for the entertainment of the numerous unemployed graduates in Arts of the Madras University who, though laymen, would, subsequent upon special education, form good substitutes, in most respects, for Medical Officers of Health, who apparently cannot be afforded.

Having abandoned the scheme for Chief Certificated Sanitary Inspectors, I laid before Government proposals for ensuring tenure of appointments and for improving the pay, status, and education of existing Certificated Sanitary Inspectors. The matter is under its consideration. Of this class of men 16 are now employed by District Boards, and 108 by Municipalities. They have also been more freely employed than formerly in temporary capacities for cholera duty, by the more enlightened of the Local Bodies. By order of Government, none but such specially trained men are now employed on plague duty. During the year, 51 men passed the practical and theoretical examination, after training in the Medical College ; so that there is now available a total of 322 men holding certificates.

The advantage of training Sanitary Inspectors is likely to be no longer confined to the Civil Department, as the Lieutenant-General, Madras Command, has adopted my recommendation to send selected British soldiers to Madras, for training at the Medical College, with a view to future service in cantonments, and Government has agreed to this being given free of cost. If sufficient inducement were offered in the way of pay, it is possible that British soldiers educated at Madras could be made available for service in cantonments and barracks in other parts of India. The men sent for training must, however, be selected with care, as the standard of general education assumed for Certificated Sanitary Inspectors is the Matriculation examination of the Madras University. It is probable that even this standard will be raised, so that only those who have passed in the "first class" will be accepted.

I have for many years made enquiries as to the existence of tuberculosis amongst cattle in this Presidency. I have not been in a position to inspect many carcasses myself, whilst the scanty information received from other officers has constantly been of a meagre nature. Nevertheless, I think it very unlikely that tuberculosis does not exist amongst cattle, as the affection is common enough amongst the poor—more especially in the large city of Madras. With the hope, therefore, of gaining evidence from the living animal, I imported tuberculin for distribution to selected officers ; but, so far, no reports of positive results have reached me.

Captain Giffard, I.M.S., supplied this office with an excellect abstract of marked nerve symptoms found by him in the severe beri-beri epidemic amongst sepoys in the Northern Circars—an outbreak alluded to in my previous report. The report is of interest, in view of the scepticism of certain authorities as to the existence of the disease in this area.

In connection with malaria, special descriptive circulars were issued to all local bodies and certificated sanitary inspectors inviting them to do their best to exterminate the anopheles, and to limit infection by the use of quinine. At the same time, I pointed to the fact that former theories in regard to the influence of surface and sub-soil drainage had gained—not decreased—in value by the new theory, whilst in the light of Manson's hypothesis as to the possibility of the existence of a second extra-corporeal form of the *plasmodium malariæ*, I included a warning against the premature abandonment of the additional theory of water infection. To several local bodies and certificated sanitary inspectors specimens of the anopheles were forwarded, to aid their recognition. These were procured for me by Mr. Nagaraj, B.A., a resident of Madras, taking an interest in entomology. He has been able to find three species of culex in Madras city that possess spotted wings, so that, without care as to other characteristics, the anopheles are not so easily identified as at first hoped. Communication by him of the fact to Major Giles showed that that authority has also found specimens in the North of India. Such specimens of culex, with one exception, as had been previously identified with spotted wings, were not of Indian origin.

The action of municipalities under G.O., No. 1536-M., dated 9th September, 1896, referring to precautionary measures against cholera, was carefully watched. There was a constant tendency to employ small and inefficient staffs—a practice, which, in view of the existence of rules duly approved by Government, gave rise to much unnecessary reference. Action under this head was considerably hampered, for the best part of the year, by disturbance of the methods of reporting to this office by local bodies, due to a ruling by the Board of Revenue. Under Government Orders, this matter has now been satisfactorily rectified.

No change in policy as to plague measures was made by Government. The "passport system" formed an important item in methods adopted and was a means of securing the detection of first imported cases in a large number of instances. The whole of the Plague Regulations were revised by Government, and were reduced to a more convenient form for reference. In doing so, the recommendations of the Plague Commission were held in mind. A pamphlet published by me privately for guidance of Plague Inspectors was accepted by Government as an official manual and was revised by me for the purpose. The Surgeon-General and the Sanitary Commissioner were directed, in consultation, to supplement Government rulings by executive directions in their respective branches. These have been completed. As a special report will be written by my successor on plague measures adopted, it is unnecessary to further enter into the subject.

The Vaccine Institute for this Presidency referred to in my last report has now been definitely sanctioned, and suggestions for plans have been handed to the Sanitary Engineer and the Consulting Architect. The question of combining this with a bacteriological laboratory remains under consideration.

Dr. Srinivasa Rao, Bacteriologist to the Mysore Government, communicated to this office the results of an important series of experiments on the comparative values of lanoline, glycerine, and vaseline as preservatives of animal vaccine, which shows my contention that lanoline is, in a tropical climate, and under ordinary conditions of storage (without ice) and of transport, the best available preservative, to be correct, and, further, that in respect to "extraneous organisms"—concerning the advantage of getting rid of which I think there exists some exaggeration of facts—their gradual extinction proceeds not only with glycerine but also with lanoline. This power was at first publicly admitted by Dr. Copeman as to lanoline, as a result of his own experiments, and then denied—apparently on the strength of Dr. Bloxall's experiments. The point of Dr. Srinivasa Rao's experiments, however, lies in the fact that he finds really sterile specimens of glycerinized vaccine are not produced by the process adopted by the Local Goverment Board as a result of Drs. Bloxall and Copeman's experiments either at the Jenner Institute or by private firms in England. He further verified Gottstein's dictum as to the impenetrability of lanoline by microbes introduced on the surface: a quality which first made me think of its suitability for vaccine preservation. Dr. Copeman quotes the growth of fungi as an objection, but, obviously, such results occur only in specimens that have been carelessly exposed. In the new Vaccine Institute difference of opinion on such points will be ignored, and both glycerinized and lanolized vaccine will be issued to District Boards, according as local medical officers may elect. Practical experience will ultimately decide between halting opinions.

The question of conservancy of towns is steadily receiving more attention from local bodies, whilst the various methods of biological purification of sewage are likely to

become popular. The people especially realize the convenience of using household sewage filters. The Civil Surgeon, Guntúr, made experiments with the dhobi platforms arranged as biological filters, which I had advised, with satisfactory, though limited, results. Certain municipalities have been asked to make experiments as to the nutrient power for crops of filter effluent and crude sewage respectively. In 1894 I advised the Municipality of Madras to filter such part of its sewage as could not be utilized on its farms, and thus prevent sewage being allowed to flow to undesirable outlets. In a communication to Government I invited its attention to this suggestion, and advised that if carried out fully it would get rid of the nuisance caused by the locally-notorious Cooum.

I sat upon a committee appointed to consider the question of sewerage of Fort St. George.

Two hundred and thirty-seven reports of sanitary inspection of towns and villages were received from District Medical and Sanitary Officers. Extracts dealing with important matters, with my remarks thereon when necessary, were forwarded to the local bodies concerned, and action by them was carefully traced.

NOTE ON PLAGUE BY THE ACTING SANITARY COMMISSIONER, MAJOR A. E. GRANT, I.M.S.

It is unnecessary, I consider, to go into details regarding the history of plague in this Presidency during the year, inasmuch as the whole matter is clearly recorded in the *Plague Returns and Narrative* submitted month by month to the Government of India by the Government of Madras. A few points, however, may be referred to in this report.

During 1900, plague followed a very similar course to that taken by it in the preceding year. The total number of attacks throughout the Presidency during the year was 895, of which 665 proved fatal. The severe outbreak in Tiruppattúr, alluded to in last year's report, was almost exactly duplicated in regard to point of time, insidious and unrecognized onset, gradual spread, &c., in the neighbouring town of Vániyambádi. These towns are also peculiar, so far as regards this Presidency, in containing a very large proportion of Muhamadan inhabitants. The majority of those in Vániyambádi are of the *Lubbai* class—the most ignorant and obstructive race, excepting, perhaps, the Moplas, in Southern India. Happily, the indigenous cases throughout the year have been confined to the Salem district.

The history of these outbreaks lends very strong support to the importance of continuing to employ preventive measures, in full, until at least one cold weather season has elapsed without the occurrence of any cases of plague. Or, to put it another way, they emphasize the necessity for undiminished vigilance, throughout the hot season, in an infected area and its neighbourhood, so that the disease may be attacked as it sinks to its minimum with a reasonable hope of success. The saving effected by reducing the plague establishment *pari passu* with the "hot weather" decline in the number of attacks, is apt to prove merely apparent and but false economy when it is found that by such procedure a way has been opened for the recrudescence of, or re-infection with, this disease, unrecognised till it has once more gained a firm foothold.

The relationship between plague and temperature has been as clearly marked as usual.

No fewer than 57 cases were imported to Bellary, Ganjám, Chingleput, North Arcot, Vizagapatam, Madras, South Canara, Nilgiris, Tinnevelly, Anantapur, Trichinopoly, and Malabar, but in none of these instances did the disease obtain a foothold.

The system of passports, observation, and railway inspection, in spite of irresponsible and superficial criticism to the contrary, worked extremely well on the whole. At Jalarpet no fewer than 114 cases were detected and detained. Nothing approaching perfection has been reached, but that a very effective check to the general spread of the disease has been afforded by means of observation and preventive circles, railway inspections and the passporting of travellers from infected areas, cannot be doubted.

It is a regrettable fact that personal observation and the privately expressed opinions of responsible plague officials go to show that it is by no means the ignorant and lower classes who alone oppose or seek to discredit the efforts of Government in these directions, and it is much to be desired that officials and other Europeans of good standing should refrain from expressing strongly-worded opinions on the "absolute uselessness" of such measures; and from exhibiting a petulance in responding to the demands of inspecting officers, which is alike undignified and uncalled for. The work of a Medical Officer at an inspecting station is far from congenial at the best; at the worst

it calls for a marvellous degree of quiet persistence coupled with tact and self-restraint. It is but reasonable, therefore, to expect that such work shall arouse not the hostility but the sympathy of those members of the educated public whose duties or pleasures entail much railway travelling.

During the year that excellent manual *The Plague Inspector* was carefully revised by its author, Lieutenant-Colonel King, C.I.E., and was constitued an official publication. Government has also sanctioned the issue of the clear and simple Sanitary Rules for Prevention of Plague in Municipalities, by the same authority, to all municipalities. In addition, the Regulations and Rules for Combating Plague have been revised and codified by Government and an explanatory appendix issued therewith. By means of these three carefully prepared publications, the whole matter has been very much simplified, and, so far as I am aware, they form by far the clearest expositions of plague regulations and procedure in India.

Sanitary Engineering.

The Acting Sanitary Engineer visited 23 towns, and the Assistant Sanitary Engineer eight towns during the year. In 1899 they visited 16 and 9 respectively. Surveys for water-supply were completed in three municipalities, and were in progress in three others. A drainage survey was completed in one municipality. Water-supply schemes for seven towns were prepared and submitted during the year. An estimate for a complete drainage scheme for Ootacamund was prepared and submitted. Improvements to the Trichinopoly water-supply were commenced and completed, and the Cuddapah waterworks were extended during the year. The scheme for the joint water-supply of Saidapet and the Mount Cantonment was still under consideration. Advice was given to the Sanitary Board in respect of 19 municipalities and 45 local fund schemes. Five type designs for various sanitary works were prepared and approved during the year. The Inspector of Steam Boilers and Prime-movers visited seven pumping stations, some of them two or more times, and made a complete examination of the machinery.

Sanitary Board.—The constitution of the Board remained unchanged. During the year the Board scrutinized the plans and estimates of 108 sanitary works. Of these, 20 were for Municipalities, 87 for Local Fund Boards, and one for the public Works Department. The total estimated value of the projects amounted to £20,230.

ABSTRACT OF REPORT OF THE SANITARY COMMISSIONER FOR BOMBAY FOR 1900.

(*Lieutenant-Colonel J. W. Clarkson, I.M.S.*)

General Population and Vital Statistics.

The census was taken on the 1st March, 1901, and it will be of interest to compare the figures obtained with those made out by deducting the deaths from the births since 1891.

In the first five years of the decade, the registered births exceeded the deaths by 549,797, and the increase occurred in all districts except Bombay City, Broach, Kaira, and Ahmedabad, in which the deaths exceeded the births by 48,544, 1,651, 8,255, and 22,854, respectively. the years 1892, 1893, and 1894 being the years in which the high death-rate occurred.

In the last half of the decade, however, owing to the bad years of 1897, 1899, and 1900, the registered deaths exceeded the registered births in all the collectorates except Dháwár, Kánara, Shikárpur, and the Upper Sind Frontier, but on the whole ten years the total diminution of population is 241,547 and the decrease is shown in the City of Bombay, every Gujarát District, Násik and Thána in the Western Registration District, and Poona in the Central Registration District.

Comparing the figures thus obtained by registration with the census figures, very striking discrepancies are observed.

A table is attached showing this. The census figures for 1901 are those furnished by the Provincial Superintendent of Census Operations and include Europeans and Eurasians, and so for purposes of comparison census figures for 1891 of Europeans and Eurasians have been added to the native population as shown for 1891. It is stated that there is not likely to be much difference between the census figures of 1891 and 1901 as regards Europeans and Eurasians, but on this point I am doubtful and should think there had been a fairly substantial increase. If this is found to be the case the difference now shown between the census and registration figures as regards the native population will be much lessened. The census figures show an increase over the registration figures in the collectorates of Thána, Kolába, Dhárwár, Ahmedabad, all collectorates in Sind and in Bombay City. In the City of Bombay the registration, especially of births, is defective, and in Sind it is known that the registration of births, especially of female infants, is below what it should be. In Ahmedabad, Thána, and Dhárwár the increase may be accounted for by immigration. It is the decrease shown in the census figures over those shown by registration which is so difficult to account for, as in some cases the differences are so large. Accepting the census figures as correct, there are two causes which may partly account for the deficiency. One is that the emigration in search of work to foreign territory, such as is known to have taken place from Ahmednagar, Sholápur, and other places after the rains of 1900, has been much larger than was calculated, and the other is that all the deaths which took place have not been registered. The Deputy Sanitary Commissioner, Gujarát Registration District, considers that this has been the case in Gujarát, and it is possible in Khándesh also, but why the difference should be so great in places like Sátára, Belgaum, and Bijápur is difficult of explanation, except it is the continued effect of emigration and deficient registration, but on the whole the difference is

not so large, and considering the agency by which registration is carried out, it is satisfactory that the difference is not larger :—

European and Eurasian Vital Statistics.

The European civil census population of 1891 in the Bombay Presidency, exclusive of cantonments in quasi-foreign territory, is 18,486. During the year 1900, 260 births and 373 deaths were recorded against 221 and 231 in 1899—a birth-rate of 14·06 per 1,000 against 11·96 in 1899 and a death-rate of 20·17 against 12·52.

The Eurasian census population of 1891 is 8,519. During the year 1900 the births amounted to 149 against 166 in 1899 and the deaths to 247 against 185, the rates being 16·20 per 1,000 against 19·49 in 1899 and 29·0 against 21·72.

The causes from which deaths among Europeans and Eurasians were recorded are given in the following table :—

Causes of deaths.		Europeans.				Eurasians.			
		1900.		1899.		1900.		1899.	
		Number of deaths.	Ratio per 1,000 of population.	Number of deaths.	Ratio per 1,000 of population.	Number of deaths.	Ratio per 1,000 of population.	Number of deaths.	Ratio per 1,000 of population.

* As the population for the cantonments in quasi-foreign territory is not obtainable, the ratio of deaths cannot be worked out.

Native Population— Vital Statistics.

Births.—In the Presidency of Bombay, including Sind, during the year 1900, there were 505,662 births registered against 685,348 in 1899. The recorded births for the year under report were less by 179,686 than the number registered in the previous year, and also less by 150,597 than the decennial mean ending 1899. By sexes there were 262,837 males and 242,825 females against 355,869 and 329,479 in 1899. In only four districts, Dhárwár, Kánara, Shikárpur and Upper Sind Frontier did the number of births exceed the deaths.

The recorded birth rate for the year was 26·87 per 1,000, the lowest for the past 10 years, against 36·42 in 1899, and a decennial mean of 35·32, a result due to the weakness induced by famine. For every 100 male births during the year there were 92·39 female births.

The number of births recorded during the year is less in every collectorate than in the previous year except in the City of Bombay and the Kánara district. It is most serious in the Gujarát districts, but all the famine-affected areas have suffered. The Deputy Sanitary Commissioner, Sind registration district, observes that : "The very low birth-rate recorded in Thar and Párkar district is probably due to the exodus caused by the scarcity which prevailed in the desert areas, and to the effects of the scarcity and to cholera."

The recorded birth-rates among the urban and rural populations of the Presidency were 23·72 and 27·30 against 26·48 and 37·80 in 1899. Except in the collectorates of Khándesh, Ratnágiri, Bijápur, Kánara, Broach, Kaira, Panch Maháls, Ahmedabad and throughout Sind, the birth-rates were higher among the rural than in the urban population. The urban rates were greatly affected by the famine and plague, but it is usual for healthy rural areas to have higher birth-rates than crowded towns.

Out of 56 towns in the Presidency, 10 had a birth-rate exceeding 40 per 1,000. Poona, Belgaum, Ahmednagar, Násik, Bombay, Thána and Karád have very low birth-rates.

Deaths.—Among the civil population in the rural, town, and cantonment circles in the Presidency, 1,318,783 deaths were registered during the year 1900. In 1899, 672,269 deaths, or 646,514 less than in 1900, were recorded. This result is chiefly due to famine.

The following statement shows the number of deaths recorded in each year since 1890 :—

1890	...	... 463,616	1894	...	... 607,179	1898	...	... 548,825
1891	...	... 513,132	1895	...	... 538,540	1899	...	... 672,269
1892	...	.. 611,742	1896	...	... 596,472	1900	...	... 1,318,783
1893	...	... 511,831	1897	...	... 749,916			

Of the total deaths registered, 706,275 occurred among males and 612,508 among females, against 355,241 and 317,019 respectively, in 1899. The death-rate per 1,000 in 1900 was 70·07 against 35·72 in 1899, and a decennial mean of 31·28. The millesimal rate of males dying to males living was 72·53, and of females dying to females living was 67·43. In 1899 these ratios were, respectively, 36·48 and 34·90. For every 100 females who died, 115·31 deaths among males were recorded, but these proportions vary considerably in the following collectorates and districts :—

In Násik	the ratio of male to female deaths was		116·79	per cent.
„	the City of Bombay	do.	133·69	„
„	Ahmednagar	do.	116·42	„
„	Sholápur	do.	117·11	„
„	Kaira	do.	124·02	„
„	Panch Maháls	do.	123·19	„
„	Karáchi	do.	127·88	„
„	Hyderabad	do.	124·46	„
„	Thar and Párkar	do.	134·89	„

The highest death-rate occurred in the Gujarát Registration District (156·47), which, with the Western and Central Districts, suffered severely from famine. The Southern and Sind Registration Districts were not nearly so severely affected by famine. The death-rates in 1900 were higher than the decennial mean in all the collectorates except Dhárwár and Kánara, and also higher than in the previous year in all the collectorates except the collectorates of Belgaum, Dhárwár and Kánara.

The Deputy Sanitary Commissioners, Western Registration District, Central Registration District and Gujarát Registration District, attribute the high mortality to famine. The Deputy Sanitary Commissioners, Western Registration District, and Gujarát Registration District are both of opinion that all the mortality has not been registered owing to defective registration and the confusion caused by the sudden and sweeping outbreaks of cholera, and the Deputy Sanitary Commissioner, Gujarát Registration District, is inclined to attribute one-third of the total deaths to immigrants. The Deputy Sanitary Commissioner, Southern Registration District, considers the chief causes of mortality to be plague in Belgaum and Dhárwár, and cholera in Belgaum, Dhárwár and Bijápur Districts. The Southern Registration District alone shows a lesser rate of mortality than in the previous year, though it is above the 10 years' mean.

The highest death-rates are shown by the collectorates of Panch Maháls (281·06), Ahmedabad (173·03), Broach (163·82), and Kaira (148·44), all in Gujarát, and the lowest is found in the Upper Sind Frontier.

In every collectorate the death-rates amongst males were in excess of those amongst females, except in the City of Bombay, Shikárpur and the Upper Sind Frontier. In 1899 the female death-rates exceeded those among males in the City of Bombay and the Upper Sind Frontier.

Comparing the birth and death-rate in each collectorate for 1900, the birth-rate was much below the registered death-rate in all the collectorates except Shikárpur and Upper Sind Frontier. In the collectorates of Shikárpur and Upper Sind Frontier the recorded birth-rates (29·54 and 28·86 per 1,000) were above the registered death-rates (25·99 and 25·42). In all other collectorates the recorded death-rates were higher than the registered birth-rates.

The Deputy Sanitary Commissioner, Western Registration District, remarks that "the outstanding features of the vital statistics of the Western Registration District for the year 1900 are the enormous increase in the registered mortality and the hardly less marked falling off in the number of births. Both are effects of the same cause, famine, which lowers the birth-rate by enfeebling the people and by breaking up families in the search for work, while in time of famine few marriages take place. The increased mortality has shown itself under every heading except plague, which is now gradually losing power in Western India. The greatest rise in mortality has occurred in Khándesh, which records a death-rate of 97·03 per 1,000 compared with 39·86 for the previous year. The death-rate, high as it is, falls far short of the actual fact, the defective registration of births and deaths in the hilly western and northern portions and the Bhil country generally making even an attempt at an estimation impossible."

The Deputy Sanitary Commissioner, Southern Registration District, remarks "the low birth-rate recorded in 1900 must be ascribed to famine and plague prevalence. The usual routine measures to obtain accurate registration were carried out. To obtain accurate data compulsory registration will eventually have to be enforced. Amongst the causes of death, plague was prominent in Belgaum and Dhárwár Districts, and cholera in Belgaum, Dhárwár, and Bijápur districts."

The Deputy Sanitary Commissioner, Gujarát Registration District, states that "the increase in the number of deaths is due directly or indirectly to famine; directly through deaths from starvation, and indirectly through the reduced condition of the people engendering a predisposition to disease."

Deaths by ages.—As regards deaths by ages, the figures show that by ratio per 1,000 of population the largest number of deaths took place in the period "under one year of age" and next in the age-period "60 years and upwards," the lowest ratio being in the period 15 and under 20 years of age relatively compared with the previous year, a by no means healthy year: the greatest increase in mortality is in the age-period 5 and under 10 years. Taking the percentage on total deaths, the age period "1 and under 5 years" gives the highest figures and then the period "60 years and upwards."

Deaths by causes.—The subjoined table shows the deaths in 1900 arranged according to the specified causes laid down by the Government of India and contrasted with the results for 1899 and with the decennial mean. The "causes of deaths" will be briefly noticed in the next section :—

Causes of deaths.	Mean for 10 years, 1890–1899.		1899.		1900.	
	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.
Cholera	23,077	1·24	8,579	·46	163,889	8·71
Small-pox	3,024	·16	1,946	·10	9,885	·52
Plague	Not available.		96,596	5·13	33,196	1·76
Fevers	382,332	20·57	228,438	12·14	543,319	28·87
Dysentery and diarrhœa ...	46,568	2·51	74,736	3·97	218,243	11·59
Injuries	6,276	·34	7,102	·38	8,224	·44
Other causes	120,076	6·41	254,872	13·54	342,027	18·17
All causes	581,353	31·28	672,269	35·72	1,318,783	70·07

During 1900 the greatest number of deaths (162,555) took place in July and the least (66,250) in December. In 1899 the greatest and least numbers occurred in March (65,190) and June (42,282).

The heavy mortality, which is shown by an increase under every heading except plague, is due to famine.

The recorded death-rates among the urban and rural population of the Presidency were, respectively, 102·33 and 65·57 per 1,000 of population against 64·10 and 31·76 in 1899.

Chief Diseases

Cholera.—In the year 1900 there were 163,889 deaths recorded as due to cholera compared with 8,579 deaths from the same cause in 1899. Every district in the Presidency was affected, the collectorate of Kánara escaping lightly with only 82 deaths during the year. Khándesh, Thána, Sátára, and the Gujarát districts suffered severely, and it is doubtful if all the deaths under this heading in the Khándesh and Gujarát districts were entered, owing to the suddenness and virulence of the outbursts.

In December, 1899, cholera deaths were reported from the collectorates of Dhárwár and Bijápur and the City of Bombay. In January of the year under report, the disease continued in the same collectorates, Khándesh being affected in addition. There were 388 deaths reported, but out of these 352 were recorded in Khándesh alone. In the month of February the same districts, except Bijápur, returned deaths, Sholápur returning one death only in addition. In the month of March the same collectorates continued to be affected, but instead of Sholápur the collectorate of Násik began to return deaths. In April the mortality was especially heavy in the collectorates of Khándesh and Násik, 8,260 deaths and 2,908 being respectively reported. During the same month, in addition to the above, all the Gujarát districts and the districts of Thána, Ahmednagar, Poona, and Sátára were affected, and the districts of Sholápur and Bijápur, in which cholera had ceased, again reported deaths. In May all the districts returned deaths from cholera except Kánara, Karáchi, Hyderabad, Shikárpur and the Upper Sind Frontier. In June the collectorate of Hyderabad was affected in addition, and in July, in which the largest number of deaths for the year was returned, all collectorates, except the districts of Kànara and Upper Sind Frontier, were affected. From August, however, the mortality rapidly diminished month by month, but deaths were reported from Kánara in this month and from the Upper Sind Frontier in September. In December 488 deaths were reported from 9 Registration Circles—Bombay City (16), Poona (3), Ratnágiri (13), Belgaum (96), Dhárwár (171), Bijápur (44), Kánara (32), Karáchi (107), and Hyderabad (6).

By seasons 106,193 deaths occurred in the rainy season of 122 days; 4,805 in the hot and dry season of 61 days; 6,870 in the cold season of 121 days; and 2,811 in the hot and damp season of 61 days.

Out of 220 rural circles or tálukas, 201 were more or less affected by cholera. In 58 rural circles the death-rate from cholera exceeded 12 per 1,000 of population. The disease principally prevailed in nine tálukas of each of the Thána and Khándesh collectorates; in five of each of the Násik, Kolába, and Karáchi collectorates; in four of each of the collectorates of Ahmedabad, Kaira, and Surat; in three of the Broach collectorate; in two of the respective collectorates of Ahmednagar, Sátára, Panch Maháls and Thar and Párkar; and in one of each of the collectorates of Hyderabad and Ratnágiri.

Out of 56 town circles, 51 were affected by cholera during the year. The death-rate exceeded 10 per 1,000 of population in 29 towns, and of these 12 are situated in the Gujarát Registration District, and among them Borsad town, where the death-rate rises to 126·90 per 1,000 of population, heads the number.

The affected area included 8,461 out of 25,143 villages in the Presidency. The highest percentage took place in Karáchi, where out of its 791 villages, 694 or 87·74 per cent. were affected. In Hyderabad, Kaira, Broach, Thána, and Surat the percentages were 66·90, 50·78, 50·12, 47·91, and 43·52, respectively, and in Sátára also out of its 1,343 villages 572 or 42·59 were affected, but in the remaining collectorates the percentages were below 40 per cent.

Small-pox.—There were 9,885 deaths from small-pox (5,198 males and 4,687 females) against 1,946 in 1899 and a decennial mean of 3,024. The mortality is the highest recorded for the past ten years. No district has been free, though some districts have been visited lightly. The Western Registration District shows the highest mortality, 64·35 per cent. of the total deaths, and of the deaths in the district the largest number occurred in the City of Bombay in the early part of the year. Both in the city and in the districts adjacent the outbreak was much increased by the large influx of strangers. In the city fortunately open airy sheds for calves, in a fair situation, are in temporary use, thus the calves were enabled to be kept healthy, and by great exertions on the part of the Superintendent of Vaccination and his staff a very large number of vaccinations and re-vaccinations (over 34,800 in three months) were performed, as the chief outbreak was in the first quarter of the year.

As regards the deaths from small-pox in the Southern Registration District, the Deputy Sanitary Commissioner, Southern Registration District, remarks that "small-pox caused 752 deaths in the whole circle as against 439 last year, which was largely due to difficulties of vaccination work in affected plague localities"; and as regards the deaths from small-pox in Gujarát, the Deputy Sanitary Commissioner, Gujarát Registration District, states that "considering the enormous influx of people from surrounding States during the famine, the number of deaths from small-pox is not large, and testifies to the good work done by vaccination staff."

According to age 28·86 per cent. of the small-pox deaths occurred amongst infants under one year of age, whilst 41·20 per cent. took place among children one to ten years, the remaining 29·94 being among persons over 10 years of age.

Fever.—There were 543,319 deaths registered under the heading "Fever," excluding plague (288,145 males and 255,174 females), against 228,438 in 1899, thus there was an increase of 314,870 deaths as compared with the previous year; the decennial mean is 382,332, which includes the deaths from plague for the past four years. The number of deaths registered from fever is the highest for the past ten years. The death-rate was 28·87 per 1,000 as compared with 12·14 for the previous year and a decennial mean of 20·57, and this includes the deaths from plague during the years from 1896 to 1899. In the Gujarát Registration District the death-rate was very high. In the collectorates of Poona, Dhárwár and Kánara the ratio was nearly the same as that for 1899. The collectorate of Panch Mahál heads the list with a very high ratio, 167·77 per 1,000, against 21·44 in 1899, and 23·26 in the previous ten-year mean. In the collectorates of Ahmedabad, Broach, Thar and Párkar, Kaira, Khándesh and Surat high ratios are observed. This result is due to famine causes to a great extent.

As regards the enormous increase in the number of deaths from fever in each collectorate in Gujarát, the Deputy Sanitary Commissioner, Gujarát Registration District, remarks that "three-fifths of the total number were returned from Ahmedabad and Panch Mahál Districts. The returns from these two districts show serious defects in registration, and fever as a cause of death is much too commonly entered. The highest recorded number of deaths from fever in any month was in May, which is a very unusual occurrence, and may be partly accounted for by the fact that in this month also the cholera epidemic reached its greatest virulence and many deaths from cholera were entered under the heading of 'Fever.' Still, a form of fever was unusually prevalent early in the year and continued throughout the hot weather. A careful watch was kept for symptoms pointing to relapsing fever, but no cases were observed, and during the hot weather a careful investigation, conducted by Captain Lamb, I.M.S., in Broach, Kaira, Panch Mahál, and by myself in Ahmedabad District, produced no evidence of this disease. It was not confined to famine workers or the poorer classes. The better classes suffered considerably in Ahmedabad City. This type of fever continued up to the fall of the rains and was quickly followed by the usual type of malarial fever, which became quite an epidemic among a people reduced in condition by a year's famine. The rain was scanty and ceased early, and malarial season attained full vigor in August and September, fully a month before the usual time."

As to the increased number of deaths from fever over that for 1899 in Sind, the Deputy Sanitary Commissioner, Sind Registration District, remarks that "the severity of the incidence was most marked in the Thar and Párkar District. The increase is attributed to the large number of famine refugees in this district, their bad state of health, and the altered conditions under which they were living."

Plague.—At the end of 1896 there had been a total of 2,909 attacks and 2,086 deaths from plague, 61,093 attacks and 46,944 deaths were recorded during 1897, 110,369 attacks and 86,191 deaths during 1898, 126,287 attacks and 96,596 deaths during 1899, and 43,064 attacks and 33,196 deaths in 1900. The incidence of this disease has been very much less in the year under review than in the two previous years. In every circle, except Karáchi, the attacks and deaths have been very much lower than in the previous year. Whether this is due to the waning of the disease, the less severe measures, inoculation, non-registration of plague deaths or the numbers of those liable to plague having been reduced from other causes such as famine, remains to be seen. The table below gives the progress of the disease by months in each collectorate for the year under report. The epidemic continued throughout the year and was at its lowest intensity in July and reached its maximum in October. Five districts, Broach, Panch Mahál, Thar and Párkar, Shikárpur and Jacobabad remained uninfected throughout the year.

† Not available

Khándesh.—This district was very lightly affected. There were 10 attacks and eight deaths in four villages.

Násik.—The plague prevailed in a mild form up to May, when it ceased, the greatest mortality (56) being in February, It reappeared in August with 30 deaths, and rapidly increased with 373 deaths in September and 756 in October ; after this it declined just as rapidly, and the year closed with 11 deaths in December. In all there were 27 towns and villages affected, and 1,688 attacks and 1,420 deaths.

Thána was affected during the whole year as in 1899. In January there were 142 deaths from plague, and the disease gradually increased until April, when the maximum number of deaths, 397, took place, and then gradually declined until July, when 32 deaths took place ; it then again increased during the months of August and September, when 249 deaths were recorded in the latter month and again gradually declined, and the year closed with 96 deaths in December. There were 51 towns and villages affected with plague, recording 2,402 attacks, and 2,046 deaths.

Bombay City.—As in 1899 the disease was prevalent throughout the year. The maximum deaths, 3,125, were reached in March, when it rapidly fell until July, giving 268 deaths, the minimum, and then again there was a gradual rise, and continued so until the close of the year, when 464 deaths were recorded. The total for the year was 17,913 attacks and 13,285 deaths.

Kolába.—There was plague in a mild form in Kolába for nine months. The highest mortality, 45, took place in January. In all there were 35 towns and villages affected, and 197 attacks and 140 deaths.

Ahmednagar.—In January there were 43 deaths, and decreased gradually till April, when it ceased. The district was practically free until the end of the year. The totals for the year were nine towns and villages, with 173 attacks and 147 deaths.

Poona.—In the Poona collectorate plague occurred in all the tálukas except Junnar. In January there were 109 deaths, after which they fell rapidly until in May, and the collectorate was free in June. There were a few cases in July. In August there was a large and sudden increase in the mortality, and continued to increase till October, when 2,353 deaths, the maximum, were recorded ; 86 towns and villages were affected, and there were 6,086 attacks and 5,086 deaths reported.

Sholápur.—The disease was on the increase during the latter part of 1899, and recorded the maximum deaths, 695, in December, but in January there was a fall, which continued until April, when only two deaths were recorded, and the district remained free till the close of the year. The totals for the year were 22 towns and villages, 1,030 attacks and 877 deaths.

Sátára.—In January there were 144 deaths, after which they fell rapidly until in May, when 8 deaths were recorded, and the collectorate was free up to the end of August. The disease reappeared in September, and continued to the end of the year with a few deaths each month. In the whole collectorate 56 towns and villages were affected, and there were 583 attacks and 424 deaths.

Ratnágiri.—In the first half of the year plague prevailed to a limited extent, while the latter half, with the exception of three deaths in October, was free. The highest mortality (106) was in March. There were 52 towns and villages affected, and 375 attacks and 287 deaths occurred.

Belgaum.—As in 1899 the disease was prevalent during the entire year. In 1900 the minimum deaths took place in June, but from that month it began to increase till October, when the maximum (1,205) was recorded. Ninety-three towns and villages were affected, and there were 6,498 attacks and 4,647 deaths reported.

Dhárwár was affected during the whole year except in the months of May and July. The year opened with 375 deaths in January, and the disease gradually declined till April, when the minimum, 35 deaths, was recorded ; it again increased rapidly, when the maximum, 380 deaths, was reached in October ; 77 towns and villages were affected, and there were 2,112 attacks and 1,681 deaths reported.

Bijápur.—In January there were 128 deaths, after which they fell rapidly until in March, when two deaths were recorded, and the collectorate was free till the close of the year. The total for the year was 26 towns and villages, 216 attacks and 178 deaths.

Kánara.—With the exception of February plague was present in a mild form throughout the year. There were six towns and villages affected, and there were 129 attacks and 92 deaths.

Surat.—In this collectorate the plague was present in every month of the year. Amongst town circles the highest number of deaths, 128, was recorded in the town of Bulsár. In all there were 17 towns and villages affected, and 387 attacks and 297 deaths.

Broach.—There was no plague in this collectorate.

Kaira.—This district was very lightly affected. There were 24 deaths in three towns and villages.

Panch Maháls.—There was no plague in this collectorate.

Ahmedabad.—In this collectorate, Dáskroi Registration Circle returned nine deaths, while 22 deaths were reported from Ahmedabad Town Circle.

Karáchi.—The increase which took place towards the close of 1899 continued in January with 57 deaths and 64 in February, when it rapidly increased, recording the maximum mortality, 1,436, in April, and declined just as rapidly as it increased. The disease ceased in June, and the district was free till the close of the year. Karáchi Town Circle suffered the most during the year. In the whole collectorate 16 towns and villages were affected, and there were 3,164 attacks and 2,446 deaths reported.

Hyderabad.—In the first half of the year there were a few deaths from plague, but the latter half was free. There were three towns and villages affected, and 101 attacks and 80 deaths reported.

In the whole Presidency there were 43,064 attacks and 33,196 deaths from plague, and 587 towns and villages were affected, as compared with 126,287 attacks, and 96,596 deaths and 2,256 affected towns and villages in 1899.

The parts most affected were City of Bombay, the Collectorates of Poona and Belgaum, and the rates of plague deaths per 1,000 in them were 16·48, 4·80 and 4·60 respectively. Karáchi came next with a rate of 4·36, and then Thána, Násik, Dhárwár and Sholápur with rates which ranged from 2·50, 1·69, 1·60 and 1·16 respectively; the rates of the remaining affected collectorates were much lower. The rate per 1,000 for the various registration districts were as follows:—

Western 3·74, Central 1·35, Southern 2·00, Gujárat ·11 and Sind ·88.

In January there were 3,695 deaths, and during March they rose to 4,631. In April the deaths fell, and continued to fall until the minimum (352) was reached in July; they rose again in August, and a more distinct rise took place in October, when the maximum 5,345 was recorded, after which they continued falling until December.

Dysentery and Diarrhœa.—Dysentery and diarrhœa caused the deaths of 119,877 males and 98,366 females, or a total of 218,243 persons, against 74,736 in 1899, and a decennial mean of 46,568; an increase of 143,507 against the last year, and 171,675 over the decennial mean.

The deaths ascribed to dysentery and diarrhœa during the eight years preceding 1897 showed only slight variations, but have since 1897 shown a great increase. In the famine year of 1897 there was a sudden increase, which is but natural in a year of scarcity, and has been repeated to an even greater extent in the present year.

The Deputy Sanitary Commissioner, Gujarát Registration District, remarks that "these diseases prevailed from the beginning of the year, and only sensibly declined during the last two months. They were most prevalent during and just after the rains, when damp and chills were added to the chief cause—unsuitable food. The consumption of badly cooked, half-cooked or raw grain, wild seeds, leaves, bark of trees, roots, &c., in fact of almost anything solid which would help to fill the void; these are the chief causes of what was really an epidemic of dysentery and diarrhœa. The famine has brought to light many new kinds of grain as food, chief among which are the endless varieties of grass seeds. At first there were two chief varieties, Samo and Ankhi-Manki, the former being obtained only from Bir land or regular grass land, while the latter is ubiquitous. Later any patch of grass was shaved close to the ground and the ground carefully swept, and the miscellaneous collection of seeds ground to a meal and eaten as cakes. It is astonishing how many hundreds of people have been able to keep body and soul together on a diet of grass seed cakes, yet considering the proportion of indigestible and irritating husk

to nutrient material in the tiny seeds, a purely grass seed diet must at any rate at first have had very deleterious effect. The consumption is so large now that the collection of grass grain has almost become an industry."

Injuries.—During 1900, 4,740 males and 3,484 females, or a total of 8,224 persons, met with violent deaths. The mortality from these causes is more by 1,112 than that reported in 1899. Of the 8,824 deaths 3,637 occurred from drowning, 984 from wounding, 955 from snake-bite, 203 from hanging, 107 from poisoning, 121 from attacks by wild beasts, and 2,217 from other causes.

Other Causes.—The recorded deaths from causes other than those specified number 342,027, of which 180,698 occurred among males, and 161,329 among females. The total for 1899 was 254,872, so there is an increase of 87,155. Under this heading all deaths are included which cannot be classed under cholera, small-pox, fever, plague, dysentery and diarrhœa, or injuries. The numbers have been increasing since 1890, and much more rapidly from 1896, and it is due—

(1) To improvement in registration so that now more attention is paid to the cause of death, though considering the agency there is room for further improvement.

(2) To plague, which has made registrars careful not to put too many cases down to "Fever," which attracts attention and enquiry.

(3) And this year to famine causes.

Sanitary Works.

During the year ending 31st March, 1900, there were 165 municipalities in the mofussil with a population of 2,196,359 souls: the total income of these municipalities, including balance in hand on 1st April, 1899, amounted to £459,667. Out of this sum £97,180 were expended on improving the water-supply, drainage and conservancy within municipal limits.

There are 23 District Local Boards with 205 Táluka Local Boards: the entire income of these Boards during the year ending 31st March, 1900, amounted to £302,862, and out of this sum £21,497 were expended on water-supply, drainage, and conservancy.

The Bombay Village Sanitation Act of 1889 has been introduced into 301 villages, or one more than the number last year. It would appear that owing to famine and plague, which claims the attention of the District Officers, no progress has been made in the establishment of village committees under the Village Sanitation Act.

Apparently no further progress has been made in the number of selected villages in which the Village Sanitary Inspection Book has been introduced, as the number stands about the same as it did last year, and this is due to famine and plague. The number of villages where the inspection book has been written up by the Sanitary Department stands at 543 against 359 of the previous year.

Personal Proceedings and General Remarks.

At the beginning of the year Lieutenant-Colonel O. H. Channer, M.B., D.P.H., I.M.S., was acting as Sanitary Commissioner for the Government of Bombay up to the 20th April, 1900. During that time he inspected in the Broach District the Poor-house, the Reservoir Work, and the Ashta Famine Relief Work; in Poona, the Poor-house and the Moshi and Girchwad Ramshet and Karkala Camps; in Ahmednagar, the Poor-house and the works at Kaparwadi, Chas, and Warulwadi; in Sholápur, the Poor-house and the Hotgi and Kondi Kegaon Works; in Bijápur, the Poor-house and the Sangogi Relief Camp and Bádámi; in Násik, the Poor-house, the Kirdi Sathe, Wasali, and Odal Works, and in Khándesh the works at Chálisgaon and Mehanbhara, and also the Collectorates of Belgaum and Dhárwár. On April 21st, 1900, I took over charge upon return from leave, and as the conditions in Gujarát were then very serious, I went up to Ahmedabad in May and inspected the works about there to enquire into the cause of the high mortality, and also Nádiad, A'nand, Thásra, and Dákor; in June, Godhra, Dohad, Mehmedabad, Broach, and Surat were visited. In September, the Ahmednagar collectorate was visited and seven

relief works inspected ; in October the Sholápur Collectorate was visited, and in December I toured in Násik and Khándesh to ascertain the famine prospects and what medical relief was likely to be needed.

Many towns were visited in the course of the inspection tours, and though the expenditure on famine was heavy, and no sanitary measures of importance save those having connection with famine works were in progress, the general cleanliness was fairly well maintained.

The famine has been reported on, and a great deal of information regarding the public health during the time is contained in the previous sections and in the appendices of this report. It may as well be stated that the rains appeared late and ceased early, and owing to this famine conditions continued to the end of the year, though not so severely as in the previous year.

As has before been stated, it is not so much the quantity of rain that falls as the way in which it falls, which is productive of the greatest benefit to the country.

In the Western Registration District the collectorates affected were Khándesh and Násik above Ghâts and Thána below. The climatic conditions were coldness in the first part of the year, followed by a rather greater heat than usual in the hot season. The rains fell much later than usual, but the fall was not evenly distributed, and their early cessation in September ruined prospects of the late crops, and this was the condition throughout the Deccan generally.

In the Central Registration District the collectorates of Poona, Sátára, Ahmednagar, and Sholápur were affected. In this group the climatic conditions were much the same. Cold weather in the early part of the year, with a hot season somewhat hotter than usual, and a rainfall not well distributed and ceasing early to the detriment of the late crop, and so relief, but not on such a large scale, had to be continued. There was immigration from Native States into Sholápur and Ahmednagar and to a less extent into Poona, but the people being hardy and thrifty and accustomed to famine conditions from the year 1897, the death-rate per 1,000 of population did not reach to twice the normal rate of the previous five years.

In the Southern Registration District the collectorates of Bijápur and Belgaum suffered from famine conditions. In Bijápur just over 50 per cent. of the population were affected, the climatic conditions were much the same as in Sholápur, and the percentage of relief was in January 1·05 of the population affected. All the relieved being workers, by the end of April the numbers amounted to 6·62, of which 4·74 were workers. Then the numbers on relief gradually declined, till near the end of November the percentage was 1·07, of which 0·65 were being gratuitously relieved. The prices of jowári and bájri were in January $22\frac{1}{2}$ and $20\frac{5}{8}$ lbs., in May $21\frac{5}{8}$ and $20\frac{1}{4}$ lbs., and in December $24\frac{1}{2}$ and $25\frac{1}{2}$ lbs. to the rupee, contrasted with an average of $45\frac{2}{8}$ lbs. jowári and $39\frac{1}{8}$ lbs. bájri in the year 1898.

The Gujarát Registration District was very seriously affected by famine. The collectorates of Ahmedabad, Broach, Kaira, and the Panch Maháls suffered throughout their entire area, and in Surat, though the famine was not so severe, 75 per cent. of the population were affected. The climatic conditions were cold in the early part of the year with a wide variation between the maximum (day temperature) and the minimum (night temperature), and to this, no doubt, was due some of the increased mortality which began to show itself in this part ; but it was not the sole cause. Then the hot weather came on, and it was hotter than usual and accompanied by a very strong hot wind blowing up clouds of dust which made it hard work for the people to fulfil their tasks. The rains set in late, practically not till July, and after September they ceased, so that famine conditions still continued, but, fortunately, the conditions were not so severe, as there was a large growth of wild grasses on the seeds of which the people supported themselves.

Immigration from surrounding Native States took place to a large extent, especially into the Panch Maháls and Ahmedabad, and these wanderers getting into poor condition before reaching relief helped to swell the mortality. No correct estimate of their numbers can be furnished, and they soon learnt to avoid stating where they came from. The mortality in all the Gujarát Districts was very high, and the causes are briefly—

(1) The practice of not storing grain, so that when their food was suddenly restricted they supplemented it with deleterious and indigestible substances.

(2) Clinging to their houses on this insufficient food to look after their cattle, and then, when the cattle died, coming on to the relief works in an impoverished condition, and then, being dissatisfied with the wage they were able to earn, wandering away again.

(3) The large influx of people from Native States. Many coming in in poor condition.

(4) The cold weather at the end of the year, and then the heat which prevailed throughout Gujarát accompanied by a hot wind.

The amount of relief given in the various districts in January varied from 1·82 in Kaira, 1·36 in Surat, 5·19 in the Panch Maháls, 6·68 in Ahmedabad to 23·88 in Broach, and this rose by the end of April to 12·68 in Kaira, 3·19 in Surat, 16·55 in the Panch Maháls. 18·78 in Ahmedabad, and 25·15 in Broach. The differences in the percentages relieved in the various districts do not appear to have had any appreciable effect on the mortality, for, leaving out Surat, the death-rate in May for Broach, which had the largest numbers on relief, is the highest in May after the Panch Maháls and Kaira, for the same month, in which district relief was the lowest, had the lowest mortality, though of course that was very high.

Towards the end of the rains, as it was apprehended that, owing to the enfeebled condition of the people, a heavy mortality from malaria might take place, distribution of free medical relief on an extensive scale was organised and continued to the close of the year. This was much appreciated by the people, and was, I consider, beneficial.

In the Sind Registration District the Thár and Parkar collectorate was affected by famine, and there was a good deal of immigration into the principal town, Umarkot, of famine-stricken people who had not made adequate provision for the march across the desert and arrived in such a poor condition as to seriously swell the mortality. The mortality, which in January was over three times the ten years mean, gradually diminished till May, when it was a little over twice the normal. In June a great increase took place, and in July it was eight times the monthly average, and then again declined till in December it was under three times the normal.

In none of the famine-affected districts did the number of births exceed the number of deaths, and a very serious decline from the previous five years' mean can be noted in most of them, due to the privations endured. The majority of the deaths have been ascribed to "Fever", and it was so wide-spread that a sharp watch was maintained for relapsing fever, but expert bacteriological research failed to detect it, and although, as our Registrars are not highly educated men, and medical certificates as to the cause of death are seldom furnished, there can be little doubt that many cases were entered under the head of "Fever" which should have been entered under other causes, yet there was a good deal of malaria present to attacks of which people succumbed more readily than at other times.

Cholera was widespread, but the deaths attributed to this are not so many as might be expected, and perhaps this is due partly to deaths being omitted when the outburst was severe and sudden, and partly that in the earlier stages at least the deaths were entered under the heading "Dysentery and Diarrhœa."

Plague did not appear in the famine camps and poor-houses, and did not, except in Poona and Belgaum, obtain much hold in the famine districts.

The deaths from starvation are given for each district in the following table :—

Deaths from Starvation.

Districts.	1900												
	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Total.

Even with the best arrangements such deaths in a widespread and severe famine are to be expected. The largest number of deaths is reported to have occurred amongst wanderers, and the Gujarát district shows the highest figures. Of these deaths by far the largest number took place in and around the town of Ahmedabad. Here there were a large number of wanderers, who objected to go to the poor-house, and when in tried to get out as soon as they could and preferred to beg, and so eventually succumbed. If they had remained in the poor-house, and gathered strength enough to enable them to work, they could have gone to a work and earned a sufficient wage to keep them. The dead were picked up by organised stretcher-parties and brought for examination before burial.

The sanitary measures taken at camps were directed to the preservation of the purity of the water supply, the selection of places for latrines and burial grounds, hospitals and wards for infectious diseases, the proper laying out of camps, and the building of kitchen shelters and poor-houses.

Medical officers as many as were available were placed in charge of camp hospitals and poor-houses, and besides treating the sick they constantly went round the camp inspecting the condition of the people, seeing to the cleanliness of the camp and the water-supply, and when considered advisable disinfecting the wells with permanganate of potash. They also saw that the food and other articles sold in the camp bázárs were good and wholesome. These camps and medical officers were supervised in turn by the District Medical Officer.

The water-supply in most of the Deccan districts was of the usual average quality, and on most of the famine camps and kitchens and poor-houses sanitary precautions were taken to safeguard it and supply it as free from contamination as possible to the people. In Gujarát, however, in certain parts the water is brackish or tends to become so as the hot weather advances. Twenty-one samples were sent for analysis from the various districts of Gujarát and 15 were pronounced unfit for potable purposes. In ordinary times, the people being in good health, do not appear to suffer from the use of the water to which they are accustomed, but with the failure of the rains the yield of water was lessened and it was probably more contaminated than usual, and had more deleterious effect upon a population whose stamina had deteriorated ; but this was a subsidiary cause, just as the effect of cold and heat acting on frames weakened by want of proper food.

It was in many cases impossible to prevent workers taking water from unauthorised sources, or bringing in unwholesome food, and so starting cholera, which when it broke out caused the people to scatter and infect other places. In the hot weather, when the people were getting low and the deaths were numerous, a longer rest was given in the time and the work lightened, and the rule regarding compulsory residence at camps was relaxed. Gratuitous relief was largely expanded during the rains to assist the cultivators in their field operations.

Report of the Sanitary Board for the Year 1900.

Preliminary.—Plague and famine again pressed hard on the municipalities last year ; and we would again draw attention to paragraph 8 of our Report for 1898. Government gave various municipalities considerable grants-in-aid for plague expenditure ; and it is hoped that the financial state of these municipalities will recover this year to some extent.

Sukkur.—The pumping machinery was thoroughly overhauled and repaired, at a cost of £300, which has resulted in one-third of the fuel expenditure being saved. It is proposed to drive a cross collecting gallery, to increase the water-supply in the cold weather, when the large spring in the original tunnel always diminishes as the river falls. It is not understood why the supply of this spring should fluctuate with the height of the river, as the temperature of the former is five degrees, or more, higher than that of the river, and the spring water is much harder, so that it must come from a considerable depth, and apparently from a subterranean source.

Hyderabad.—The new engines at the river lift have been working very satisfactorily and with a very large saving in fuel. Plans and estimates for improved settling tanks, and for a pier to carry the suction pipe out into the river, have been approved of by Government, and sent to the municipality. If Government, in the Military Department, would only pay the arrears due for extra water supplied to the troops (a matter which has now been under discussion for same years, and is believed to have been at last finally settled), the municipality would have funds to start these works. Plans and estimates

for filter beds, a high level reservoir in the Fort, and for covering in the Fort lift reservoir, are still under consideration. The drainage scheme is postponed for want of funds.

Karáchi.—The sewage farm is said to have been more profitable last year; but its management, as a *true* sewage farm, seems to have decidedly deteriorated since the departure of the late Superintendent. There is, apparently, no reason why it should not be as profitable as the Madras sewage farms, if properly managed.

Ahmedabad.—The drainage scheme, prepared by Mr. B. Latham, was practically shelved for over a year, as the Public Works Department Executive Engineer could not spare time to work out the necessary alterations. It has lately been taken up again; but we think that it will be quite impossible for the Executive Engineer to carry out a work of this importance satisfactorily and without recurring delays, in addition to his own heavy work, even if he is given an assistant, who will naturally have had little, if any, experience of such work. A Special Engineer, with drainage experience, should be employed. The sewage farm has much improved under the care and management of the present Superintendent. The municipality have now sent him to study the crop systems at the Surat Government Farm, and the Karáchi Sewage Farm; and as he is an intelligent man, with an interest in his work, he will probably gain valuable information.

Kaira and Mehmadabad.—The plans and estimates for the water-supply projects for these two towns have been prepared by the Sanitary Board, and will be submitted shortly.

Yeola.—The waterworks have been practically at a standstill for over two years, although about half the work had then been done. The Public Works Department Executive Engineer has had no time to push on the work, and the municipality (as is always the case) will not provide the extra taxation for the necessary funds, unless they are specially and continuously urged.

Ahmednagar.—The Kapurwadi Tank was not completed as a famine work before last monsoon, consequently no water was stored over the aqueducts, and the water-supply to the town and cantonment (as anticipated in our reports for the last two years) will probably be a matter of serious difficulty this hot weather. The work is *now* practically done; and the project for completing the distribution in the remaining two-thirds of the town will be sent in shortly. It would be advisable to have a similar system of distribution, under pressure, in the cantonments.

Poona.—The drainage and water-supply projects, prepared by the Sanitary Engineer, were revised in accordance with the advice of Mr. Santo Crimp, and finally approved of by the municipality and by the Government of Bombay. They are now before the Government of India, as they can only be carried out by a loan on liberal terms; this, it is to be hoped, will be given, as the works are very urgent and necessary for the health of both the city and cantonments.

The results of the small sugarcane experiment at the Kirkee Government Farm were confirmed by that at the Manjri Government Farm (the latter being at the site of the proposed municipal farm), and in each case the effluent was found to produce about ten per cent. more sugar than poudrette, which is the standard manure for sugarcane in the neighbourhood of Poona. The Government Agricultural Chemist was deputed to make full analyses of the cane, juice, and soil; and his report may be expected shortly. The experiments are being continued; and it is under contemplation to carry out a large practical test at Manjri on ten acres of land; but this should not delay the early commencement of the Poona Sewerage Works, the urgency of which is shown by the fact that during the first half of last year, when plague was absent from the City of Poona, the death-rate (which has been increasing yearly), was from 50 to 60 per 1,000. The experiments are only to prove how the effluent can be most profitably utilised; but as the drainage scheme will take three years to carry out, this knowledge can be ascertained during that time. If the profits are only half what the small experiments show, there can be no risk to Government; and looking to the heavy yearly cost of the measures for counteracting plague (which the city cannot bear in the future), we submit that even if there was some risk, it would be more than justified, and would probably be cheaper in the end. We would, therefore, most strongly urge that the sewerage works in the city should be commenced at once, leaving the question of the final disposal of the sewage to be settled hereafter. Although such farms have not paid in England, it must be remembered that water is an absolute necessity for cultivation in India, whilst it is only an added difficulty in England.

Sholápur.—We would beg to refer to paragraph 16 of our Report for 1898. Nothing has yet been done towards providing a second pumping engine, and the danger, of course, increases yearly, as the engine is now being worked 50 per cent. more than what it was designed for. The Public Works Department Executive Engineer has not even yet had time to work up the sewage scheme, which is urgently wanted. The source of the water-supply of Sholápur is the Ekruk Tank, from which the water passes to the pumping station by an open channel about $4\frac{1}{4}$ miles long. Naturally, there is great danger of contamination to the water in this channel ; and we would urge the necessity for filter beds at the pumping station, as at Poona, and for the protection to the channel of supply.

Belgaum.—The water-supply project for the town and cantonments, prepared by the Sanitary Board, has been transferred by the Bombay Government to the Madras Military authorities, as the troops are under that Command. The very scanty supply in the wells at present shows the urgent need for such a scheme, as this scarcity is, more or less, recurrent every year. Unless there are early rains the situation will probably become very difficult, if not dangerous, this hot weather, as at Ahmednagar.

Regarding the other towns and projects referred to in our Report for 1898, we can only repeat what we have said in paragraph 10 of our Report for last year.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF THE PORT OF BOMBAY FOR THE YEAR ENDING 31ST DECEMBER, 1900.

The following tabular statement gives a summary of the shipping of the Bombay Port and the work in connection therewith, for the year ending 31st December, 1900 :—

Vessels including Country Craft.	Number of Vessels inspected.	Number of Persons inspected, including Crew on Vessels.	Number of Native Crew and Third Class or Deck Passengers disinfected during the year.	Number of Vessels disinfected.	Number of Persons Vaccinated.	Number of Persons segregated or rejected.	Diseases and Number of Cases of each.					
							Plague.	Cholera.	Small-pox.	Measles.	Chicken-pox.	Jigger.
Entered	156	23,192	5,607	46	2,064	145	11	5	12	3	—	125
Left	65,734	1,149,858	71,555	—	—	17,169	59	2	1,347	19	17	—
In Harbour during the year ...	76	—	—	76	713	—	14	78	33	6	2	—
Total for 1900 ...	65,966	1,173,050	77,162	122	2,777	17,314	84	85	1,392	28	19	125
Total for 1899 ...	65,822	1,193,339	48,349	87	32	17,662	155	1	2	7	7	168

It will be seen that 65,966 vessels of all sorts with 1,173,050 crew and passengers, including those who arrived from certain infected ports, were examined during the year. The clothing and bedding of 71,555 native crew and third class or deck passengers who embarked on vessels for ports out of India were disinfected against the clothing and bedding of 44,864 disinfected during the year preceding. This increase in disinfection work is due to the fact that the luggage of the native crew, deck and third class passengers (with the exception of troops) proceeding to ports out of India was disinfected, whereas for 1899 all native crew's clothing and bedding were disinfected from 13th February 1899 and that of deck and third class passengers from 14th June 1899. The baggage of 987 returning pilgrims, 2,877 deck passengers arriving from Jigger-infected ports and 1,743 crew and passengers of other infected vessels which arrived in Bombay was disinfected. The total number of persons vaccinated was 2,777 against 32 during the previous year, as there were 1,392 cases of small-pox detected at the outward and inward inspections and on board the vessels lying in the harbour during the year 1900. The number of plague cases detected was 84 against 155 for the year preceding. There was an increase of cholera cases, the number being 85, while during the year 1899 there was only one case. There were 125 jigger cases—43 less than in 1899. Most of the rejections at the medical inspections were allowed to return to the city, which accounts for the few cases of plague recorded during the year 1900.

The following table gives details regarding vessels which entered the port during the year:—

Year.	Total Number of Steamers and square-rigged Vessels which entered Bombay Harbour from Ports other than Indian Ports.	Number of Passengers only.	Total Number of Native Sailing Craft which entered Bombay Harbour from Ports other than Indian Ports.	Number of Passengers only.	Total Number of Steamers and square-rigged Vessels which entered Bombay Harbour from Indian Ports.	Number of Passengers only.	Total Number of Native Sailing Craft which entered Bombay Harbour from Indian Ports.	Number of Passengers only.
1900 ...	622	10,562	274	158	1,697	477,116	34,673	21,231
1899 ...	527	25,660	250	484	1,375	309,915	44,267	6,001

As there is no record kept of the crew on most of the vessels entering the Port the numbers are not given in the above table. There were 462 troops, 987 Mecca pilgrims and 507,156 passengers, principally from ports near Bombay, making up the total of 508,605 passengers as compared with 342,060 during the year 1899.

The number of ships which had infectious disease on board on or before entering the harbour is given in the following table :—

Class of Vessels.	Number of Ships.	Total Number of Crew and Passengers inspected.	Number of Passengers from East Africa disinfected on account of presence of Jigger among them, and those from other vessels for infectious diseases.	Diseases and Number of Cases of each.						Number of Persons Vaccinated.
				Plague.	Cholera.	Small-pox.	Measles.	Chicken-pox.	Jigger.	
Troop-ships	—	—	—	—	—	—	—	—	—	—
Vessels from Jigger-infected Ports.	27	4,947	2,877	—	—	—	—	—	125	—
Other Vessels	19	5,236	1,743	11	5	12	3	—	—	2,064
Total	46	10,183	4,620	11	5	12	3	—	125	2,064
1899	32	7,624	2,623	4	—	1	2	7	168	32

Six steamers which entered the harbour had 11 cases of plague at the time of arrival or during the voyage. The cases were sent for treatment to the Plague Hospitals in Bombay, and the effects of the crew and passengers as well as the ships were thoroughly disinfected in accordance with the Venice Convention Regulations. There were five cases of cholera (of which three died) on board the steamer "St. Ninian" during her voyage from Calcutta. Two cases were found on board the steam-ship "Massilia" and were removed to the hospitals on shore. The vessels were thoroughly disinfected. The bilges were pumped dry and cleaned; the drinking-water tanks on board were emptied and disinfected with potassium permanganate solution before they were allowed to be filled with a fresh supply of drinking-water. Eight steamers had in all 12 cases of small-pox and two vessels had 3 cases of measles. All these cases were removed to the hospitals and the ships disinfected. Those of the unprotected crew and passengers among whom small-pox occurred were vaccinated. Enteric fever is not noticed as it is not one of the infectious diseases under the Act.

Out of the 70 vessels with 8,728 crew and passengers which arrived at Bombay from Jigger-infected ports on the South-East Coast of Africa, 27 vessels had 125 persons suffering from Jigger and ulcers due to Jigger at the time of arrival. They were removed to the Gokuldas Tejpal Hospital for treatment. The crew and passengers on infected Jigger-ships had their clothing and bedding disinfected before they were allowed to mix with the general population.

Examination and disinfection of incoming vessels were carried out according to the revised rules issued by Government under their Notification No. 1645–P., dated 13th March, 1900. Accordingly, all arrivals from plague-infected ports, viz., Karáchi, Persian Gulf Ports, Hedjaz, Glasgow, Port Said, Alexandria, Aden, Cape Town, Mauritius, Hongkong, and other Eastern ports were inspected up to the 5th of April,

1900, after which date only "infected vessels" were inspected in accordance with letter No. 2128-P., dated 31st March, 1900, from the Secretary to Government. This letter authorized the Port Health Officer not to inspect "Healthy Vessels" arriving at Bombay from plague-infected ports until such time as the City of Bombay is considered free from plague, which would be for the purposes of this order, when the number of plague deaths reported in the published returns falls below 25 in a week. In the case of infected vessels, Government directed that the passengers and crew need not be detained, if they were apparently healthy; but Rule VIII. (1), (3), (4), and (5) of the new rules—a copy of which is given below—should be carried out, and similarly, in the case of "Suspected Vessels," Rule IX. (1), (2), (3), (4)—a copy of which is also given—should be followed.

Rule VIII.—"Infected Vessels," or vessels so classed, will be dealt with as follows, when Bombay is free from plague, and may be so dealt with at other times at the discretion of the Health Officer :—

(1.) The sick will be disembarked under the directions of the Health Officer and sent to the camp or hospital, whether ashore or afloat, appointed for the purpose.

(3.) The soiled linen and personal effects of the passengers and crew which, in the opinion of the Health Officer, may be considered as infected, shall be disinfected in accordance with the rules contained in the appendix.

(4.) The bilge-water will, after disinfection, be pumped out, and a fresh supply of drinking water will be stored on board.

(5.) All parts of the vessel, which have been occupied or frequented by plague patients, will be disinfected under the supervision of the Health Officer, and any other parts of the vessel may also be disinfected at the discretion of the Health Officer.

Rule IX.—"Suspected Vessels," or Vessels so classed, will be dealt with as follows :—

(1.) Passengers and crew will be medically examined by the Health Officer.

(2.) The soiled linen and personal effects of the passengers and crew which, in the opinion of the Health Officer, may be considered infected, shall be disinfected in accordance with the rules contained in the appendix.

(3.) The bilge-water will, after disinfection, be pumped out and a fresh supply of drinking water will be stored on board.

(4.) All parts of the vessel, which have been occupied or frequented by plague patients, will be disinfected under the supervision of the Health Officer, and any other parts of the vessel may be disinfected at the discretion of the Health Officer.

The following table furnishes the total number of vessels, crew and passengers examined on arrival at Bombay, including the ships with the returning pilgrims from Jeddah, and those which arrived from Jigger-infected ports :—

Months	Number of Vessels inspected.			Number of Persons inspected.							Number of Persons segregated.			Number of Plague cases found on arrival at Bombay.
				Passengers.		Crew.		Total.						
	Number of Steam-ship and Square-Rigged Vessels.	Number of Native Sailing Craft inspected.	Total.	Steam-ship and Square-Rigged Vessels.	Country Craft.	Steam-ships and Square-Rigged Vessels.	Country Craft.	Number of Passengers.	Number of Crew.	Number of Passengers and Crew.	Passengers.	Crew.	Number of Passengers and Crew.

The medical examination of the crew and passengers of all vessels which left Bombay for ports out of India was carried out by day, on shore, in sheds specially arranged for that purpose. Out of 1,149,858 outward bound crew and passengers inspected, 19,534 or 1·70 per cent. were prevented from sailing. Most of the rejections were turned into the town. The remainder were sent to the Port Observation Camp, where 59 of them developed plague.

Out of 65,734 outgoing vessels, with 562,139 crew and 587,719 passengers examined during the year, 234 vessels with 26,195 crew and 18,756 passengers left for Aden, or ports in the Red Sea and Europe ; 642 vessels with 36,166 crew and 28,319 passengers for other ports out of India, and the remaining 64,858 vessels with 499,778 crew and 540,644 passengers for Indian ports, including Burma.

The disinfection of the clothing, bedding, and any suspected articles of native crew (excluding Japanese crew, who are specially exempt from this operation) and of the third class or deck passengers and native servants who sailed on vessels bound for ports out of India, was carried out as in the previous year at Malet Bandar, where the port health stove was situated, up to 7th September, 1900. On the 8th September, 1900, the stove was removed to the shed specially constructed for disinfection purposes near Prince's Dock, where the kit of the persons mentioned above was disinfected, while the kit of the crew and passengers, who sailed in native sailing craft for foreign ports, was disinfected by means of the municipal sterilizer at the Modikhana Hospital.

The clothing and bedding of 50,452 native crew and of 21,103 third-class or deck passengers were disinfected during the year.

The native crew of vessels proceeding to ports out of India are, as a rule, inspected three times—firstly, before embarking, so as to meet the letter of the Convention ; secondly, when their clothing and bedding are being disinfected the day before they sail ; and, thirdly, just *immediately* before the vessel sails.

The sanitary condition of all outward bound vessels, including native sailing craft, was, as a rule, carefully attended to. All of them were examined and found to be in a satisfactory sanitary condition, and were so certified in the bills of health issued to them. The crew's quarters were painted or limewashed before departure. The 'tween decks and holds of ships in ballast were cleaned before leaving the port, and the 'tween decks of coal ships were thoroughly washed down and in most cases limewashed, or disinfected with a solution of carbolic acid. This was necessary, as the holds of such coal ships are used for the purposes of nature by the coolies, numbering from 500 to 1,000, who discharge the coal. The bilges of native craft were generally clean at the time of inspection ; but those that were found to be dirty or containing filthy water had to postpone their departure until thoroughly cleaned.

Infectious Disease on Vessels in the Harbour.—All the steamers, square-rigged vessels, and native craft which became infected while at sea or among whose crew and passengers plague developed after their arrival in port, also the dock labourers found on vessels and coolies removed to plague hospitals from the docks and bandars are enumerated in the table annexed. All these vessels and those in the second table on page 159 were thoroughly disinfected according to the Venice Sanitary Convention and Indian Ports Act Rules.

Port Observation Camp.—The area of land occupied by this camp from the date of its erection, viz., 16th January, 1899, up to 31st August, 1900, was 25,090 square feet. On 1st September, 1900, the land was curtailed to 17,296 square feet, as such a large space was not required owing to most of the persons rejected having been turned into the town. Among the outgoing passengers and crew, who were sent to the camp, 59 developed plague. They were transferred for treatment to the plague hospitals in the city. All the sheds in the camp were thoroughly disinfected twice a week with the standard solution of perchloride of mercury, and when a plague case was removed to a hospital the shed in which it developed was at once disinfected with a solution of perchloride of mercury and was not used for some time after. One hospital assistant, one ayah, and one sweeper form the establishment of the camp. The services of the latter were not utilized, as the sweeping of the camp was carried out in accordance with arrangements made with the Public Health Department of the Bombay Municipality. One of the senior medical officers was detailed in turn every month to supervise the general working of the camp.

Persons sent to the observation camp were kept there until their temperature fell to normal, or until it was certain that the symptoms from which they were suffering were not due to plague.

Disinfection of Ships and Infected Cargo.—There were 122 infected vessels of all sorts disinfected during the year under the personal supervision of the Health Officer of the Port, or his staff, assisted by the harbour police. Arrangements were made by the Resident Transport Officer and the Senior Naval Officer for carrying out the Port Health Officer's recommendations for the disinfection of marine and naval ships on which cases of infectious diseases occurred.

The steamships "Bisagno," "Raffaelo Rubattino," "Domenico Balduino," "Okara," and "Rajah" landed at the docks and at Carnac Bandar damaged cargo, viz., 320 bags of grain called mug, a large quantity of potatoes, six bags of flour, and two bundles of senna leaves. The superintendents of Victoria and Prince's Docks, the Preventive Department, or the agents of the vessels called upon the Port Health Officer to examine the damaged cargo. Accordingly Officers on the Port Health Staff were detailed from time to time to examine the cargo, who after examination condemned the articles in question and certified them to be either a nuisance or unfit for human consumption.

On six occasions it was found to be absolutely necessary to disinfect infected cargo.

General Health of the Shipping.—During the year 916 persons connected with the shipping were admitted into the various hospitals in the city suffering from ordinary disease. The St. George's Hospital admitted 614 Europeans, of whom 15 died; the Jamsetjee Jijibhoy 83 natives, of whom four died; and the Goculdas Tejpal 219 natives, of whom 23 died. The diseases were chiefly due to ague, beri beri, syphilis, rheumatism, diarrhœa, cholera, small-pox, measles, bronchitis, &c. The Medical Inspector of the Royal Alfred Sailor's Home reported one case of plague, which occurred among the family of the Superintendent of the Home. There were no cases of any other infectious disease in the Sailors' Home.

The Coroner of Bombay held one inquest on a man who died from the effect of mephitic gas and 21 inquests on persons who died from accidents other than bilge poisoning on board ships.

Red Sea Pilgrim Traffic.—During the year 987 pilgrims returned from Mecca *via* Aden by four vessels. The ss "Naderi," with 448 pilgrims from Jeddah, which arrived in this harbour on the 11th of May, 1900, landed a case of plague at Aden and had five deaths from natural causes during the voyage. According to the rules laid down regarding an infected pilgrim ship, all the pilgrims were kept under observation for 10 days before being allowed to proceed to their homes up country and beyond the frontier. The well-to-do and influential persons, who travelled first-class on the vessel, were allowed to pitch their own tents and use their own furniture in the port health camp.

The baggage of all returning pilgrims was disinfected in the Port Health Disinfecting Stove. Pilgrims whose homes were up-country or beyond the frontier were not allowed to enter the town, but were sent direct from the ship to their homes by rail at the Government expense. The pilgrim traffic from Bombay to Jeddah has been stopped owing to the prevalence of plague in the former place since the year 1897, and consequently no vessels with Mecca pilgrims left this port for Jeddah during the year.

Emigration Traffic.—There was no emigration traffic this year as it has been suspended since the year 1897, owing to the prevalence of plague in the City of Bombay.

Sanitary state of the Harbour and Foreshore.—Owing to the pressure of work the usual close inspection of the harbour and foreshore was not made during the year.

Epidemic of Cholera, Small-pox, and Plague.—20,577 persons are admitted to have died in the city from plague, cholera, and small-pox during the year, viz., cholera 4,273, plague 13,286, and small-pox 3,018. Plague and small-pox existed in a virulent epidemic form from January to May inclusive, while cholera raged from June to September inclusive.

At the commencement of the outbreak of cholera in the city there were 19 deaths in the month of May among the crews of the native craft which lay at Malet, Carnac, and Modi Basins. These craft bring vegetables, fruit, and other fresh supplies for the Bombay market. Some of these basins are foul at low water, as the municipal sewers containing nightsoil discharge into the Carnac and Modi basins. Government ordered a bacteriological examination of water in these basins in their Resolution No. 3338, dated the 26th June, 1900. Accordingly 12 samples of sea water from the Carnac Basin and Modi Bay were sent for analysis to the Director-in-Chief, Plague Research Laboratory, Government House, Parel. The result of the examination by Professor Haffkine has been reported to Government in this office letter No. 2429, dated the 19th September, 1900. Professor Haffkine's opinion is quoted *verbatim*, as follows:—

> The two rather important features, viz.:—
> (1) In the faculty of a peptom culture turning red when mixed with a strong acid and

(2) of a suspension of bacilli being clumped under the effect of the serum of an immunised animal. The comma bacilli cultivated from water samples Nos. 5 (Middle of Carnac Basin), 6 (Harbour end of Carnac Basin), and 11 and 12 (about 100 yards of sewer discharging into Modi Basin) showed themselves different from typical comma bacilli isolated from cholera patients.

They may thus be either degenerated cholera microbes having lost the above two faculties, or else micro-organisms belonging to the same tribe of comma-shaped bacilli as the cholera microbes.

Our experience up to the present leads us to the conclusion that such non-cholera commas (?) are to be found only in places where cholera exists; and if they really belong to species in themselves harmless from the point of view of that disease, they at any rate indicate the presence of conditions favourable to the life and development of the cholera species of comma-shaped bacilli.

A water or locality containing such microbes ought consequently to be pronounced dangerous to the surrounding inhabitants.

Nightsoil has now ceased to be discharged into the basins and the Port Trust has arranged for the dredging of them.

The rigorous nature of the examination enforced on each individual who left this Port, combined with the disinfection of the clothing and bedding of all native crew and third class and deck passengers bound for ports out of India, lessened to a considerable extent the number of suspiciously ill persons presenting themselves for medical examination owing to the fear of being detained. For this reason very few fully-developed plague cases were found at the time of inspection.

Whenever any of the crew or passengers who were prevented from sailing on a vessel bound for a foreign port developed plague, the fact was communicated to Government, with a view to telegraphic intimation being given to the authorities at the first port of call. In cases where plague occurred among persons prevented from sailing on vessels bound to an Indian port, the fact was notified by the Port Health Officer to the next port at which the vessel was due to call.

With the exception of two (British India Steam Navigation Company and Hall Line) no lines of vessels that left Bombay met with any vexatious delay owing to quarantine regulations at foreign ports. This speaks volumes for the faith of Foreign Governments in the efficiency of the measures adopted by Government to prevent the spread of plague from Bombay by sea.

During the year 59 persons affected with plague were not permitted to sail on outgoing vessels; 14 persons, on inspection, were found to be plague-stricken on vessels and native craft in the harbour, docks, and bandars; and 11 cases occurred on vessels on or before arrival at Bombay from other infected ports, making a total of 84 plague cases in connection with the harbour.

There is a falling off in the number of plague cases detected during the year as compared with previous years, but this is due to the fact that most of the rejections during 1900 were turned into the town and were, therefore, lost sight of, while in 1898 and 1899 the rejections were kept under observation for some time in a camp. In addition to the plague cases 85 cholera and 1,392 small-pox cases were detected during the time that these diseases raged in an epidemic form in Bombay. The majority of the cases were among native passengers, and were detected at the medical examinations which take place on shore prior to the embarkation of crew and passengers.

Plague has unfortunately broken out at foreign ports, but in no instance can the outbreak be traced to the crew or passengers on vessels from Bombay. The all-important question of infection by cargo or rats was carefully considered by the late Plague Commission, but no satisfactory conclusion was arrived at. The fact that plague has broken out at various ports, only among people who worked cargo or who resided near the docks, would tend to show that the outbreaks were due to cargo or possibly rat infection.

Plague in India continues to be of the bubonic type, and so long as it continues so, there is a probability that foreign and European ports where the people wear boots or shoes will escape being attacked by a virulent and wide-spread epidemic of bubonic plague.

ABSTRACT OF THE REPORT OF THE CALCUTTA MUNICIPALITY FOR 1900-1901.

(*R. T. Greer, Esq., Chairman.*)

Health.—The excess of deaths over births and the large immigrant population in Calcutta are noticeable features. In the opinion of the Health Officer the large number of immigrants, mostly unvaccinated, tend to the encouragement of the periodical recurrence of epidemics of small-pox and the importation of cholera. After making allowance for the increase in the population, and possibly defective registration of deaths, there is reason to believe that the general mortality has been progressive, in spite of the various measures which have been taken to improve the sanitation of the town. Insanitary dwellings and over-populated buildings in congested areas are the chief factors in this result. The main hope for improvement lies in the opening out of the town by wide streets, and the enforcement of the Building Regulations to check the further erection of insanitary dwellings. Any effective scheme for the construction of main thoroughfares for the improvement of the health of Calcutta must necessarily be drastic, and involve a heavy expenditure. The limited resources of the Corporation are taxed at present to a considerable extent by the necessity to carry out the important main drainage schemes, and the supply of a continuous water-service. The public are awaiting the action of the Government in assisting the Corporation in this vital work for the health of the city.

The completion of the main drainage works should bear fruit in the immediate improvement of the health of the large population of the suburban area where the surface drains are at present a standing danger. Unfortunately operations have been checked in one important section for a reconsideration of the plans, and some delay is inevitable.

Births and Deaths.—The birth-rate for the year is shown as 12·7 per 1,000, the death-rate being 43·5. Many births apparently escape registration, though the number is not so great as these figures would seem to indicate. It is hoped that the scheme for the reorganisation of the work of the Health Department will bring about an improvement under this heading. The year was unhealthy, an exceptional heavy fall of rain in September inducing an outbreak of cholera, while an increase appears in fever and bowel complaints and plague. The infant mortality is remarkable, amounting to 748 to every 1.000 births registered amongst the Muhamedans in the town area, and to 443 per 1,000 of children under one year of age throughout the city. Early marriages and the insanitary conditions of life are the main causes assigned for these lamentable statistics.

Excepting during the abnormal floods in September, there was nothing unusual in the incidence of cholera during the year. A difference of opinion exists as to the connection between the rainfall and the disease. The introduction of a continuous service should lead to the correction of any deficiencies in the existing pipes, as well as to the provision of an ample supply of good drinking water for the inhabitants.

The Health Officer considers the period under review to be a bad fever year, and represents the statistics which show a low mortality from this cause to be fallacious owing to wilful misrepresentation to escape the suspicion of plague and its attendant consequences. His remarks regarding the influence of the water-supply and drains in the causation of malarial fever are interesting (*see* page 172).

Sanitation.—359 service privies were connected with the sewers during the year, a comparatively small advance when the existing number of the former, 52,701, is taken into consideration. The total number of premises connected with the public sewers at the close of the year was 31,295, 625 having been added in 1900-01.

Sixteen insanitary tanks and 45 wells were filled up during the year. The Health Officer has refrained from strenuous action in this direction in view of the want of a constant water supply. The preliminary steps have been taken to carry out this measure, and a greater improvement may be expected hereafter in removing these insanitary spots.

The work of filling up of wells and tanks calls for continued attention. Outbreaks of cholera are commonly traceable to these sources, while, according to modern theories, malarial fever is largely due to the action of anopheles mosquitoes, which find a suitable breeding-ground in them.

The extention of the unfiltered water supply will tend to clean the surface drains and flush the sewers, and the substitution of connected for service privies will do much for cleanliness and healthy surroundings.

Measures for a general surface drainage system will follow the completion of the main drainage scheme in the locality served by the sewers. No more pressing want exists in the suburban area, as the drainage at present is lamentably deficient.

The Re-organisation Scheme.—The re-organisation of the Engineering, Conservancy and Health Departments was undertaken by a special sub-committee towards the close of the year, and the result will appear in next year's report.

It may be noted that the sub-committee recommend decentralisation, the amalgamation of the Conservancy and Engineering Departments, and the division of Calcutta into four districts, each fully equipped with a district office under a district engineer, health officer and building surveyor.

Street Refuse.—The returns show that 377,848 tons of refuse have been removed during the year, the greater part being carried by train to the Salt-water country, and the remainder being burnt in the Goragatcha Incinerator, or deposited on a dumping-ground at Dakhuria. The work done appears to be in excess of the out-turn of any previous years.

The question of substituting incinerators for the present mode of removal by train has been fully discussed, and the Commissioners have decided to invite tenders on specified conditions for the erection of two incinerators as an experimental measure. Opinion is divided as to the advantages of the present system. The existence of loading platforms on the side of a main road is a constant nuisance to the locality. The transfer of the Municipal Railway line to the canal area has been suggested, the expense being a serious hindrance. The platform near the Campbell Hospital is specially objectionable, and action has been taken to find another site.

The Filtered Water Supply.—Special interest was taken by the Commissioners in the purity of the supply, and in the weekly chemical analysis of the water. Improvements have been carried out at the filter beds in regard to the surface drainage and the cleansing of the filter sand. Arrangements have been made for the systematic bacteriological testing of the filters with a view to checking deficiencies in the beds. A good potable water has been supplied.

The number of bacteria present in the water was comparatively small for the greater part of the year, and increased during the rains. The prevalence of bacillus coli-communis is ascribed to the pollution of the river by storm-water running off the surface of riparian *bustees*. It is impossible to cut off the source of the pollution, and an improvement of the filtering arrangements is the only remedy. The quantity of water supplied during the year amounted to 7,505,096,520 gallons, a daily average of 20,561,908 gallons. The gross cost amounted to 2·64 annas for 1,000 gallons. The daily average pressure at the pumping stations ranged from 66 to 45 feet.

The total mileage of filtered water mains and services amounts to 315 miles, 183 in the town and 132 in the suburban area. 592 feet of 3-inch pipes were laid down, and also four new standposts. Attention has been given to the question of introducing a continuous service. The inconvenience to the public is extreme from the want of a sufficient quantity of drinking water, and action is being taken to prepare a scheme to meet this need. An extraordinary waste at present takes place by leakage from pipes, faulty ferrules, and carelessness in the storage of water. The existing supply from the filter beds appears to be sufficient, but an increase of pressure is required to keep up a constant service, and measures are necessary to check waste. The current year should witness the introduction of the preliminary operations for a continuous service.

Unfiltered Water.—The supply is furnished by two pumping stations at Mullick's Ghât and Watgunge, which provided daily an average of 12,554,794 gallons and 554,596 gallons respectively. The length of the unfiltered main and services amounts to 156 miles; 118 miles in the town and 38 in the suburban area.

Ground-hydrants number 5,680, and there are two bathing-platforms, 56 public urinals, 35 public latrines, and 31 night-soil depôts in connection with the unfiltered water supply system.

Suburban Drainage.—The Engineer considers that good progress has been made during the year in the work connected with the storm-water and sewage outfall.

In the town storm-water outfall a large quantity of earthwork has been excavated from the third section of the reservoir, and the foundation of the outfall sluice has been completed up to its floor-level. The accommodation-bridges, which had been taken in hand during the last financial year were completed in the year under report.

In the suburban storm-water outfall a large quantity of earthwork has been excavated from the reservoir section, and the outfall sluice at Byntolla has been practically completed. One accommodation-bridge has been taken in hand.

The high-level sewer from Palmer's Bridge has been practically finished for a distance of about 2,900 yards, except the syphons and the road-crossings. Half of the High-level Sewer Road has been completed.

About 3,500 feet of the invert of the combined sewage channel have been finished, 910 feet of the sides being completed.

Drainage and Construction.—There is nothing specially noticeable in the work done under this heading, the extent of the operations being comparatively small. 277 feet of underground sewers were completed during the year, 1,246 feet were reconstructed, and 987 feet of surface drains were constructed. 800 feet of kerb and channel stones were set and 608 feet were regraded and reset. 20 sewer man-holes were constructed, and also 7 lamp-holes, and 121 gully-pits. 3 flushing-chambers were made and 4 yard-gullies and 14 bathing-platforms were repaired. 1 ventilating-shaft was erected as well as 2 night-soil depôts. 8 public latrines and 3 urinals were repaired. 1 urinal was constructed and also 1 hackney-carriage stand.

House Drainage.—460 house plans were prepared during the year, and 775 copies were supplied to the public. 625 premises were connected with the public sewers.

Bustee Improvements.—Little progress appears in the work of bustee improvement.

The total expenditure is shown as £2,257, of which £821 appear as compensation for land for roadway, and £1,294 for the construction of roads and sewers in connection with them. The Corporation make liberal grants for bustee improvements, recognising the importance of such measures for the health of the town. The current year should witness a development of these operations.

Model Dwellings.—The question of housing the working classes has received some attention and funds have been provided for the erection of model dwellings for this purpose. The most suitable style of building at present to hand is that which has been adopted by the Bombay Improvement Trust. Two wealthy landowners, Babu Sita Nath Roy and Babu Janoki Nath Roy, have set an example by undertaking the erection at their own expense of one of these buildings on *bastee* land in their possession in the south part of the town, and this work is now in progress. The experiment is an important one, since the demolition of *bastees*, without provision for the occupants, tends to aggravate the evils of overcrowding in the neighbourhood.

The congested state of a large part of the town from ill-constructed and insanitary houses has been recognised by all parties, and there is a general feeling that heroic measures are needed to open up wide thoroughfares bringing light and air to the localities. The Corporation is prepared to undertake its share of liability for this public duty according to its means. The enforcement of the tram-service by the substitution of electric for horse-traction, and the extension of the system should help to remove the labouring population to the suburbs and relieve the congested interior of the town.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR 1900.

(*Dr. J. Nield Cook.*)

The new census figures show an increase of 161,927, or 23·74 per cent. on those of 1891. The increase is about proportionately divided between males and females. It is principally seen in the town wards, in many of which it is over ten thousand. As there was previously little or no room for expansion in these wards, great density of the population has resulted, the number of persons per acre varying, if we except Waterloo Street, from 111 to 282, the average density of the population of London being 60·9. 282 per acre is equal to 180,480 per square mile. These figures show the extreme importance of dealing with the question of housing the working classes, which will be dealt with in another part of this report. The increase in the population cannot be considered as a natural increase due to the excess of births over deaths, as during the decade there was an excess of 108,153 deaths over births. The increase must therefore be entirely ascribed to immigration. If the decrease in the population due to the excess of deaths over births and the actual increase in the population, as shown by the census figures, be added together, we find that 270,080 more people came into the town than left it during the decade. The fact that Calcutta has such a large floating population affects its public health in many ways. Immigrants are for the most part young adults in search of work. Taking this into consideration in connection with the fact that the female population is comparatively small and consequently the number of children born is small, we have an age and sex population that should give an extremely low death-rate. On the other hand it is probable that many of these immigrants come to the town in an impoverished state and easily succumb to the prevailing diseases, though this is by no means generally the case, and from what I have seen of the labour market in Calcutta every able-bodied man can earn a fair living wage. The large number of immigrants in the town predisposes to the epidemics of small-pox that periodically recur, as many of these country people are unvaccinated and we have been unable to enforce even primary vaccination in the case of adults. Cholèra is frequently imported by immigrants who sometimes form foci for localised outbreaks. The overcrowding and the filthy conditions under which the poor live in a climate that exaggerates the evil effects of insanitary conditions lower the resisting power of the population and favour the spread of infectious disease.

The mortality of the town and suburbs together for the decade just completed and the preceding one cannot be compared as the suburbs were only added in the year 1889. The mortality of the town area from 1881 to 1890, however, averaged 12,056 deaths per annum, whilst that for 1891 to 1900 averaged 15,197, which shows an increase after making all allowance for the increase in the population. The four quinquennial periods into which the last 20 years may be divided give the following average mortalities for the town alone, 12,478, 11,635, 13,721 and 16,673. I cannot avoid the conclusion after making allowance for increase in the population and possibly defective registration of deaths in the past that the mortality has been progressive, in spite of all the work that has been done and the money that has been spent to improve the sanitation of the town. This is only what might be expected, as an insanitary town tends to become more insanitary the longer it is occupied, and this tendency is increase by overcrowding of the population. I am of opinion that nothing short of very drastic measures of sanitary reform involving a heavy expenditure will be of any avail to check this increasing mortality, as good thoroughfares must be made and insanitary areas condemned and cleared as preliminary measures. Three diseases have made their appearance during the decade of which so far as I am aware there is no previous record in Calcutta, Influenza, Cérobro-Spinal Fever and Bubonic Plague. Influenza has spread amongst all classes during nearly the whole of the decade, and has accounted for a considerable number of deaths from diseases of the lungs, particularly pneumonia. Cerebro-Spinal Fever, which

has been shown to be identical with the Cerebro-Spinal Meningitis that occurs in Europe, has occurred principally in jails and emigration depôts. One medical officer informed me that he had seen 106 cases in the last few months, and that most of them ended fatally. Cases have also been recognised amongst the general population, but it is impossible to say to what extent the disease has occurred, as more than half the people die without being seen in their last illness by any qualified medical practitioner, and the disease is not one with which the practitioners generally are well acquainted. My predecessor first reported plague in Calcutta in 1897, but his cases were not accepted by the Government medical officers, so I am unable to say whether they were true bubonic plague or not. I first saw cases of plague in April, 1898, and it has recurred year by year since then with increasing intensity, showing a seasonal prevalence in the early months of the year and nearly disappearing when the rains set in in June. The most hopeful sign about it is that the case mortality is now much lower than it was, a feature that is not uncommon before the disappearance of an epidemic of infectious disease.

Meteorology and the price of food.—Coming to the year of 1900 I find nothing likely to exercise an appreciable effect on the public health in the meteorological conditions until the third quarter, when the floods occurred in the month of September, the rainfall for that month being 45·55 inches against an average of 10·18 inches. The floods were followed by a sharp outbreak of cholera, 255 deaths being registered under that head between the 17th and 30th of that month. A marked increase in the mortality from fevers and bowel complaints is also shown to have followed the floods. There can be little doubt that exposure, chill and want of proper food and means to cook it acted as predisposing causes of disease. A sharp rise in the mortality from fevers and bowel complaints is noticed, and an inquiry that I made showed that there was a considerable increase in the mortality from diseases of the lungs. The weekly death-rate of the whole of Calcutta rose to 82·8 per thousand per annum for the week ending the 29th September, and that of the suburbs to 148·7. The price of food fluctuated somewhat, being higher than the previous year in the 1st and 3rd quarters and lower in the 2nd and 4th.

Births.—The total number of children born exclusive of still-births was 10,773, which gives a ratio of 12·7 per thousand per annum. There is no doubt in my mind that a considerable number of births escape registration, and I do not see how this can be rectified unless the midwives are brought under control by being placed on a register and not allowed to practise unless they are registered, their registration being conditional on their giving information of births in all cases attended by them. At first, as I have recommended on previous occasions, all practising midwives might be licensed and trained ones given a special form of certificate. If no new midwives were registered unless they held a certificate of competent training, in course of time the ignorant midwife would disappear in Calcutta as completely as the Mrs. Gamp type of nurse has disappeared in England.

Deaths.—The total number of deaths was 36,728, which gives a ratio of 43·5 per 1,000 per annum, the average number of deaths for the previous ten years being 22,684. Of the difference of 14,044 plague accounted for 8,354 and suspected plague for a part of the remainder. Making all allowance for this exceptional cause, it is evident that the year was an unhealthy one in Calcutta as it was in Bengal generally. The deaths are shown according to their causes and the localities in which they occurred in the table below. The localities where the highest mortality occurred were Ward 2, Coomartolly, with a death-rate of 51·7, Ward 5, Jorabagan, with a death-rate of 62·8, and Ward 18, Hastings, with a death-rate of 62·6. I am unable to understand the high rates of mortality in Hastings, a considerable part of it being occupied by middle class Europeans. I attributed them to the former census having underrated the population, but the new census makes the population even smaller than before. I have referred the matter to the census officer who has kindly promised to investigate the causes of the decrease in the census population of this quarter. The place compares favourably with most parts of the town and suburbs as regards sanitation, and no serious epidemics have been reported to me as having occurred there. The deaths are registered mostly under fevers and all other causes. The high infant mortality in Calcutta deserves special note. It amounted to 443·2 deaths under one year of age to every 1,000 births. Amongst the Mahomedans in the town area it reached the unheard of figure of 748·6 deaths to every 1,000 births registered. It is for the most part due to the conditions under which the people live being unfavourable to life, and ignorance of infant

hygiene. I believe that early marriage also conduces to it, as when an immature woman marries she frequently brings into the world one or two weakly children. I should like to see the more enlightened natives take up such questions and do something to enlighten their more ignorant countrymen and reform their habits and customs. As regards the marriage question there are signs that public opinion is on the move, though the obstacles to be overcome are great, but so long as the care of the sick is for the most part in the hands of ignorant men and women with no knowledge of rational medicine or nursing, ignorance will take its annual tribute of young lives. During the year there were 443·2 deaths under one year to every thousand births. There is one very noticeable feature about the age groups, and that is the heavy incidence of mortality on the adult population which I can only attribute to the plague epidemic. As usual the death-rates of females of marriageable age are appreciably higher than those of males of the same age. It may be that the female population in these age groups is underestimated from the natural tendency of the oriental to conceal everything connected with his women.

The principal diseases.—The following statement shows the mortality from the principal diseases compared with the average of the previous five years.

Statement of Deaths from different causes during 1900.

Cholera.—The rise in the spring closly followed the mean of the previous five years, and may be regarded as a seasonal rise. The rise in June was due to a large influx of pilgrims from the *Rath* festival at Puri. The opening of the new railway facilitated the importation. The sharp rise in September was connected with the floods. It occurred principally in the suburbs, and I believe that it was due to flood water getting into the mains. This is the only occasion on which I have traced a connection between an outbreak of cholera and the use of the filtered water supply for drinking purposes. The general history of an outbreak is that a number of cases are imported from some place of pilgrimage, the water of a tank or tanks, or it may be a well, becomes infected, as can be shown bacteriologically, and infects some of the people living round who use it for bathing, washing vessels and plates, and perhaps for other domestic purposes. As soon as the source is discovered a police guard is placed over the infected supply, and that particular localised outbreak comes to an end in a few days, though similar outbreaks may have started elsewhere. So it goes on sporadically, and the severe general epidemics characteristic of infection of a public water-supply are now unknown in Calcutta. It occurs mostly in the outlying parts of the town where tanks and wells abound. The water of the Hooghly river and of the canal that surrounds Calcutta are sometimes found to contain cholera vibrios, and at such times cases are found to occur amongst boatmen and others using that water.

Plague.—This disease having been taken out of the scope of my administration as Health Officer will be dealt with by the Special Health Officer appointed to administer it.

Diarrhœa and Dysentery.—The exciting causes of these diseases are still obscure. The course of their seasonal prevalence generally closely corresponds with that of cholera. This may be due to the similarity of their predisposing causes and also to deaths from cholera being registered under this head.

Fevers.—The bulk of the cases in which death is registered under this head are malarial, but the class includes many other diseases in which a high temperature occurs, such as typhoid, influenza, pneumonia, and not improbably some febrile diseases yet unclassified. It will be impossible to ascertain even approximately how many people die

from true malarial fever so long as the majority die without being seen by any one capable of making a correct diagnosis. I have had it in mind for some time past to apply the spleen and blood tests in several of the poorer parts of the town to get a further indication of the prevalence of malaria, but have postponed it as the people are still inclined to look upon anything new as an occult plague measure designed for their injury. It would appear from the chart and tables that the mortality from fevers was below the average. I believe this to be fallacious, for when plague operations were commenced in the town the registered fever mortality fell considerably and that under all other causes rose in a more or less proportionate degree; and this has continued ever since, pointing to wilful false registration to prevent the suspicion of plague and consequent inquiries, and perhaps disinfection. The mortality from fevers has shown a marked increase not only in Calcutta but in other large Indian towns since the introduction of a fairly abundant water-supply. This is easy to account for on the modern theory of the causation of malarial fever through the instrumentality of the mosquito, as the daily introduction of a few million gallons of water provides pools and places where the air is cool and moist during the hot dry season, conditions eminently favourable to the existence of that pestiferous insect, and drainage operations have not as a rule been commensurate with the introduction of water into the towns. As evidence of this I may mention that I have not unfrequently found anopheles breeding in the waste water from stand-pipes. They also breed in the hot weather in small tanks containing much organic matter and vegetation that abound in the outlying parts of the town, being only partially kept down by the fish and tadpoles which prey upon them. With the advent of the rains they become much more generally distributed over the town in rain water pools or puddles. In a few instances in which cases of fever occurred in good European houses larvæ were found in close proximity. I received abundant evidence all over the town that the year under review was a bad fever year, and this was confirmed by the medical officers in charge of large hospitals and public institutions. It was especially prevalent in the neighbourhood of the docks. The Port Commissioners and Messrs. Bird and Company wrote to me complaining that the work of coaling was seriously interfered with by an epidemic of fever among their coolies. I visited the place and found these coolies to be housed in good cooly lines and supplied with filtered water. Their immediate surroundings were clean. The fever was distinctly malarial. The cause of this prevalence of malarial fever was easily traced, for a stagnant ditch was found to run the whole length of the lines at a distance of a few feet from the huts, and the water of this ditch contained abundance of anopheles mosquito larvæ. As the fully developed insects hatched out they would naturally go straight into the huts, feed on the blood of fever cases, become themselves infected and transmit the infection to previously healthy persons. Messrs. Bird and Company on my suggestion procured same barrels of tar with which the ditch was treated under my direction. The action of the tar was not altogether successful, though it undoubtedly destroyed large quantities of larvæ and so limited the production of mosquitoes. The results as regards the prevalence of fever amongst the coolies were disappointing, as for a month the average daily number of cases showed no diminution. Indeed, immediate results cannot be expected in such cases, as the mosquitoes that have been bred will live for several weeks in the huts or houses and the incubation of malaria before symptoms appear is generally not less than a fortnight and may be longer: moreover, a chill or overfatigue will induce an attack for a long time after the parasite has gained admittance to the body if the patient is not thoroughly cinchonised. In two months the fever cases were reduced to half what they were when the experiment was tried, and the coolies themselves said that the fever was much less. Before the floods fever was particularly bad in a bustee near the docks known as the Noolpara bustee, so much so that the people got much alarmed at the heavy mortality. The bustee was low and ill-drained and I found anopheles larvæ swarming in every rain water puddle. The floods came and washed nearly all the anopheles larvæ out of the town. I visited the bustee shortly afterwards, and the people imformed me that the fever had practically disapeared.

Small-pox.—Small-pox no longer causes the very severe epidemics in Calcutta that it did in the past, but it accounts for far more deaths than should be possible in a properly vaccinated town, the principal reasons for this being the imperfect registration of births, the floating character of the population and that vaccination is not compulsory until the second year of life. It presents a cyclical curve attaining its maximum every five or six years, after which it subsides through most of the people who are susceptible and who have not been protected by vaccination or by a previous attack becoming immunised by

an attack of the disease. The last severe outbreak was in 1895, when it accounted for 2,220 deaths, the attacks being in all probability five or six times that number. The curve is now again reaching its highest point, the deaths in 1900 reaching 1,010. Judging from the severity with which it has prevailed during the first quarter of 1901, which is the period of its greatest seasonal prevalence, the number will be higher this year. There is a great tendency to conceal the cases. In 1900 with 1,010 deaths, only 1,598 cases were discovered. As the case mortality from small-pox never has been anything like 64 per cent., it is apparent that a large number of cases escape discovery with its resulting disinfections and vaccination of contacts, and the disease has every chance of spreading. In cases where the patient has no proper accommodation, he is removed compulsorily to a hospital. The parts of the town most affected were Ward 5, Jorabagan, Ward 6, Cooloolola, and Ward 8, Jorasanko. In consequence of the extra work entailed in making inquiries to discover cases, disinfecting premises and vaccinating contacts and any others who were willing, with the consent of the Chairman and Commissioners, my staff was temporarily strengthened by the appointment of 5 disinfecting gangs, each consisting of a Sub-Inspector and 5 men, and 3 male and 3 female Vaccinators.

Prevention of disease.—It is evident from what I have written that there is in Calcutta an enormous waste of life from preventible causes. The means of prevention are in most cases sufficiently obvious, but there are two obstacles in the way of carrying them out. One is the want of money and the other is ignorance combined with prejudice. Thus, in the case of cholera, all that is required is to extend the filtered water supply and cut off all sources of impure water by filling up tanks and wells. But many of the tanks, of which I suppose there are 1,000 or more in Calcutta, are owned by comparatively poor men who have not the means to pay the cost of filling them. Even if they were all willing to comply with our notices and had sufficient money, it would be a matter of great difficulty to find the earth required for the purpose, unless a canal was dug in the neighbourhood of Calcutta, and a light railway constructed to bring in the earth dug out. As regards plague I reported before the first case appeared in Calcutta that isolation, segregation, and disinfection, could not be carried out in such a way as to be effective in a large Indian town, and that the only measures which afforded a prospect of success were the extermination of rats, by preference by inoculating them with a disease non-pathogenic to man, and prophylactic inoculation. It is more than three years since I made this recommendation, and I see no reason to modify it: indeed, I do not think that the town will be free from the pest until the people have sufficiently overcome their prejudices to accept one or both these measures. As regards small-pox, it is well known that it has disappeared in European countries in proportion as vaccination has been enforced. The same result would follow here if we could persuade every man, woman, and child to be vaccinated. But in this case it is ignorance and prejudice rather than want of funds that opposes us, and there is every reason to anticipate that this obstacle will gradually fade away if vaccination is zealously but judiciously pushed. It is now accepted by nearly all medical men who have seriously studied the subject that the so-called malarial fever is an infectious disease or group of diseases caused by animal parasites in the blood which are conveyed from the sick to the healthy by the mosquitoes known as anopheles, these parasites being sucked up with the blood to multiply in the body of the mosquito and gain access to his salivary glands, and finally to be injected into the blood vessels of a fresh human host. Bearing this in mind it will be seen that preventive measures to be successful must more or less follow the following lines which have now been laid down:—

(*a*) The early treatment of cases as they occur with quinine and methylene blue, which have a specific action in destroying the parasites in the amœboid stage of their development before they reach maturity.

(*b*) The isolation of cases in mosquito-proof houses or curtains to prevent the mosquitoes gaining access to them and becoming infected.

(*c*) The use of curtains by the healthy in order to prevent themselves being bitten and infected by mosquitoes.

(*d*) The filling up of tanks and excavations where anopheles mosquitoes breed, levelling the ground and improving the surface drainage.

So far as Calcutta is concerned, the first and third of these measures will only be adopted by a comparatively small number of people. The fourth and last measure is then the only one which offers any real prospect of relief. I believe that an active policy on these lines backed up with sufficient funds by the Commissioners would in a few years' time considerably reduce the prevalence of anopheles mosquitoes in the town and the

mortality from malarial fever. In course of time I should not be at all surprised if even the poor people came to realise the connection between mosquitoes and malaria, and blocked up the openings of their huts at night with pieces of muslin net. I have indeed occasionally seen a rudely made mosquito curtain over the charpoy or bed in a native bustee hut. So far as regards the prevention of malaria among Europeans, it has recently been shown by Stephens and Christophers that they are much less liable to contract the disease if they live at some distance from the huts occupied by natives. This is an additional reason for clearing the bustees in the Chowringhee area and making provision for the occupants elsewhere.

From the above remarks it will be apparent that apart from the fluctuations in mortality that occur everywhere, but more markedly in an insanitary tropical town, I believe that the causes of the high mortality in Calcutta are of a more or less permanent character, but are to a great extent preventible by appropriate measures efficiently carried out. I am of opinion that the opening up of the town by broad thoroughfares, the better housing of the people, the abatement of overcrowding, which is impossible until proper provision is made for housing the poor, the filling up of tanks, wells, and all places where water can stand, completing and improving the drainage, and extending the supply of filtered and unfiltered water are the measures indicated, and that until considerable progress has been made in carrying out these measures any improvement that may be made in the conservancy of the town, the abatement of nuisances, and the control of food supplies will have comparatively little effect in reducing the mortality. Unfortunately these measures would involve so large an expenditure as to be far beyond the borrowing power of the Corporation, and such measures as the Commissioners have hitherto been able to undertake have only been partial and ineffectual. At a recent meeting of the Legislative Council of His Honour the Lieutenant-Governor of Bengal it was stated by the Secretary to Government, Municipal Department, that Government had in hand a scheme for opening up the town with wide thoroughfares at a cost of about 9 crores of rupees. Such a scheme properly carried out should effect a great improvement in the public health and facilitate other sanitary measures.

Vaccination.—The reorganisation of the Vaccination Department on the lines recommended by me and adopted with some modifications by the Commissioners was partially carried out, a better class of men being brought into the Department as vacancies occurred. The total number of vaccinations done during the year was 27,374, the largest number that has ever been done in Calcutta, except in 1895, when a severe epidemic of small-pox occurred. The number of primary vaccinations was 15,210, of which 14,570 were children. This is the largest number of primary vaccinations done in Calcutta in any year. As the number of primary vaccinations is considerably larger than the number of births registered in the town, there can be no doubt that most of the children born in the town are vaccinated, though as we cannot take any action to enforce vaccination until the completion of the first year it results that most of the children are vaccinated somewhat later than is generally the practice elsewhere. The percentage of success in primary vaccination excluding the unknown was 95·0. I believe that this low figure was due to the inferior quality of the lymph supplied at times from the Government Animal Vaccine Depôt, as with glycerised pulp obtained from the Depôt of the Madras Municipality in 133 cases my vaccinators obtained 100 per cent. successful. In the interests of the town vaccination I think it is desirable that the Calcutta Municipality should have its own animal vaccine depôt, as the Madras Municipality has. The percentage of success in revaccinations was 44·6. As I have pointed out on previous occasions the manner in which vaccination is carried on in Calcutta leaves much to be desired. Instead of the calf being placed on a special table frequently washed with disinfectants, it is thrown on the ground in a porch, verandah, or room used for a variety of other purposes, as no funds have hitherto been provided for doing the work in proper style. Considering that vaccination is compulsory, I am of opinion that it should not be carried on in a way to disgust people, but that neat depôts should be constructed in different parts of the town that could be kept clean and aseptic, that appropriate tables should be provided for the calves, and accommodation for the people awaiting their turn. A good deal of the vaccination done now is done in the bustees with lanoline paste. This has its advantages for the bustee people generally are so casual that no amount of threatening or prosecution will induce them to bring their children to a depôt at a stated time. Babu Janmejay Chowdry, B.A., L.M.S., who was appointed Deputy Superintendent in charge of the Vaccination Department, did good work and infused some energy into his vaccinators, fully justifying his appointment.

The filtered water supply.—Under Section 243 of the new Municipal Act the Chairman

is required to test the purity of the filtered water once every week, and to lay the result before the General Committee. Great interest was shown by the Commissioners in the weekly reports giving the chemical analysis of the water, and I was asked to add weekly bacteriological examinations to supplement the chemical analyses. As the Commissioners wished for a comparison with the other Indian drinking waters, the Municipal Chairmen of several large Indian towns were asked to send reports showing the analysis of their drinking water, and several were received, from which I was able to report that the water-supply of Calcutta compared favourably with that of other large Indian towns. An examination of the analysis of the filtered water for a number of years shows that the total solids, hardness, and chlorides are considerably greater in amount during the dry season than during and immediately after the rains, which I attribute to the much greater dilution with rain water which occurs during the latter season, when flood water passes rapidly off the surface instead of percolating slowly through the soil. With the exception of August, when traces of it were found, the water contained no free ammonia during the year. The albuminoid ammonia varied from ·0024 to ·008 parts per 100,000. The water contained no nitrites, and the quantity of nitrates was small. So, chemically, the water may be pronounced a good potable water. During a great part of the year the number of bacteria present in the water did not exceed 100 per cubic centimetre, but during the rains they increased enormously, so as to be on some occasions uncountable. I attributed this to the filter beds, which in the dry season would run for six weeks or so without being cleaned, becoming rapidly clogged during the rains with an adhesive deposit which did not settle in the settling tanks, so that they had to be cleaned about every six days, and were never in use long enough to become thoroughly efficient bacteriologically. During the rains we also found that bacillus coli communis was present in the filtered water. It was found in the river water, the settling tanks, and the outlet wells of the filter beds. As this bacillus is commonly taken as a danger signal shewing pollution of a water-supply I was asked to give a full report on the matter, and attributed its presence to storm-water running off the surface of riparian bustees and carrying it into the river, where it found conditions suitable for its multiplication ; as it did not appear practicable to cut off the sources of pollution, our only prospect of freeing our water from its presence lay in improving our filtering arrangements. This bacillus has continued in the water ever since, all through the dry weather following the rains, and I have also found it in the Howrah water-supply taken from the other side of the river. Mr. Silk, Sanitary Engineer to the Government of Bengal, and also a member of the General Committee, and I were then asked to make suggestions for improving the water-works, which we did. Our principal recommendations were that cattle should be excluded from the compound, that the sand taken from the filters be washed with filtered water in mechanical washers instead of with unfiltered water with coolies walking about in it and stirring it up with *kodalies* which is the present practice, and that the filters be worked by head which as a rule should not exceed three and should never exceed six inches. Mr. Silk also suggested systematic bacteriological testing of all the filters, so that any bed which was found to be letting too many bacteria through could be put out of work. The General Committee held a meeting at the water-works, where everything was explained to them, and subsequently accepted our recommendations. To carry out the last recommendation I proposed that the Medical Officer at Pulta should be trained in making cultures in the Municipal Laboratory, that a room be fitted up for him at Pulta with the necessary apparatus, that all the material be prepared in the Municipal Laboratory, and sent down to him in a box with duplicate keys, and that he should make cultures from the 36 filter beds, two from each at a time, twice a week and send them in the box to the Municipal Laboratory where the estimation would be done. These proposals were accepted by the General Committee, and will be carried out as soon as the apparatus required is obtained. The Medical Officer has already been trained in his work.

Besides the filtered water, 51 samples of Hooghly river water, and 50 samples after settling, and 46 samples from tanks and wells which it was proposed to require the owners to fill up, were chemically analysed in the laboratory by the two analysts to the Corporation, and altogether 239 samples of water were examined bacteriologically. Cholera vibrios were found in 19 samples of tank and well water, but never in the filtered water supply, though it was tested for them every week.

ABSTRACT OF THE REPORT OF THE MADRAS MUNICIPALITY FOR 1900-1901.

(*Lieutenant-Colonel G. M. J. Moore, President.*)

Births and Deaths.—During the year 1900 the total number of live births registered in Madras City was 20,672, against 18,220 in 1899. The ratio per 1,000 per annum calculated on the census population of 1891 was 45·6, against 40·2 in the previous year. This is the highest number of births ever recorded in this city. The number of still births registered during the year was 536, a proportion of 2·5 still births to every 100 born alive. The male births numbered 10,615 and the female 10,057, giving a proportion of 105·5 males to every 100 females.

Population.—The provisional census figures obtained fulfil the expectations felt at the time of writing under the above heading in last year's report. It was pretty certain that the census of 1901 would show an increase and that increase could only be due to immigration. The calculation based on the annual rate of increase per unit of population during the decade 1881–1891 gave the probable number of the population in March, 1901, as 513,300 persons. The enumeration showed this to be in excess of the real number by 3,900, so the rate of immigration during the two periods 1881–1891 and 1891–1901 may be taken to have been about the same, since the difference between the actual and the estimate is fully accounted for by the excess of deaths over births during the latter period by 4,409. There was an excess of births over deaths during the period 1880–1890 of 354 and the census of 1891 showed an increase of 53,741 over the census of 1881. The excess of deaths over births during the period 1890–1900 was 4,409, and the census of 1901 showed an increase of 56,879.

Census.	Males.	Females.	Difference.
1871	194,676	202,876	F. + 8,200
1881	200,170	205,678	F. + 5,508
1891	225,817	226,701	F. + 884
1901	257,298	252,099	M. + 5,199

Madras is slowly, very slowly, conforming to the rule of rising towns. The female population, once in excess, is now in defect on account of males being attracted to the town to work in shops and factories. The more factories there are started in the town the greater disproportion may be expected, until the time comes when women also will begin to labour with their hands, as men do. Then the excess of males will tend to be reduced, and the numbers of the sexes to be more equalised. With the decrease in the proportion of women a concomitant decrease in the number of births must be looked for; while the influx of presumably strong and healthy young males must have a certain influence on the death-rate which cannot be entirely neglected. Compared, however, with the enormous disproportion seen in towns like Bombay, that of Madras seems almost infinitesimal, and it may be well thought that a total disregard of it will not lead to serious errors in conclusions based on uncorrected figures.

Mortality.—During the year 1900 there were 20,937 deaths registered in Madras, with a ratio of 46·2 per 1,000 calculated on the census population of 1891, against 17,248, or a ratio of 38·1 in the previous year, the average for the decade being 18,477·8. Out of

the 20,937 deaths registered, 10,610 occurred among males and 10,327 among females, giving a proportion of 102·7 to 100. The number of deaths according to nationality was, Europeans, 98 ; Eurasians, 433 ; Native Christians, 891 ; Hindu, 17,182 ; Mahomedans, 2,328 ; and others, 5. The ratios per 1,000 are 35·7 among Christians, 41·8 among Hindus, 43·7 among Mahomedans, and 8·4 among "others," against 30·4, 38·6, 40·5, 6·7 of the previous year.

During the year under report the number of deaths from fevers was 5,898 against 3,317. Fevers have reached the usual level. The deaths from measles were 280 against 291 in the previous year, and from dysentery and diarrhœa 2,842 and 566 against 3,000 and 520 respectively. The deaths from small-pox were 46 against 34 ; from cholera, 632 against 23 ; and from plague four imported cases against four.

Statement of Mortality from the prevalent diseases in 1900 *contrasted with that of* 1899.

Years.	Plague.	Small-pox.	Measles.	Fevers.	Dysentery and Diarrhœa.	Cholera.	Total.	Other Causes.	General Total.	Ratio per 1,000.
1899	4	34	291	3,317	3,520	23	7,189	10,059	17,248	38·1
1900	4	46	280	5,898	3,408	632	10,268	10,669	20,937	46·2
Average for 10 previous years	1·3	51·2	444·6	5,765·5	2,971·4	456·4	9,690·4	8,787·4	18,477·8	40·8

Mosquitos and Malaria.—Anopheles mosquitos have now been found in all the eight municipal divisions. It was judged to be a futile task to attempt to catalogue all the collections of water within municipal limits in which the larvæ could be found, since those already known cannot yet be dealt with ; but incidental observations have been sufficiently numerous to justify the assertion that wherever a suitable collection of water exists, whether it be a tank, well, pool, or swamp, there will anopheles larvæ be found at some period of the year. A large number of mounted specimens of fully developed mosquitos of both genera which were caught in Madras, supplemented by a collection received from the District Medical Officer of the surrounding district of Chingleput, were taken to England to be classified and named by Mr. Theobald, but his list has not yet been received.

Later on a further batch was sent to Lieut.-Colonel Giles, I.M.S., for a similar purpose, but no news as yet come from him either.

Although A. larvæ were to be found so easily, it was extremely difficult often to find the winged insect in native houses in the day time, though in one or two European houses and in the Madras Club they could be obtained almost as often as required. Coach houses where hack bandies are kept were the surest find, and if the insides of the bandies were searched between six and eight in the morning, before they were taken out for the day, a fair number of gorged females could often be caught in test tubes.

Though a considerable number of wild females thus caught were dissected between September, 1900, and March, 1901, not a single one was found to contain the developing parasite either in the stomach or the salivary glands. This only bears out the conclusion arrived at on other grounds, namely, that only a small percentage of the female anopheles flying about can possibly be dangerous. The medical officers in charge of the three general hospitals on request were kind enough to send the approximate addresses of some of the patients admitted with enlarged spleens and undoubted malaria. The actual residences of as many of these as possible were traced out, and the surroundings examined with a view of accounting for the attacks. In comparatively few instances, however, was the source of infection indicated by finding breeding places for the larvæ on the premises in the shape of a pool or unused well, but in a certain number the source was obvious. In a town, at any rate, it does not appear to be necessary that the breeding place should be very close, for anopheles can be, and actually are, transported in closed carriages for many miles during their torpid state in the day time. They will cling tenaciously to the cloth-lined interior of a brougham, notwithstanding the jolting, for a drive of three or four miles in the morning, and may be still found in *situ quo ante* after returning home in the evening. On one occasion a particularly torpid individual was

carried about for several hours in an Elwood topi on the owner's head ; it did not stir when the topi was carelessly thrown on a table, and only flew away when poked up towards evening after a further journey on the head of the owner of the topi. Theoretically, therefore, persons living in ordinarily healthy localities can be infected by the bite of a mosquito which has been by some means transported several miles. Such accidental attacks would probably only be mild ; and it is only when severe chronic cases which are suffering from the effects of repeated infections are met with that the cause must be looked for locally. It need not be in the very house, a single unused well containing garbage will supply enough anopheles to infect people here and there in several of the adjoining streets. It is not necessary either that the actual number of anopheles flying about should be large enough to annoy or even attract the attention of the people residing there. In fact, in the narrow wells found in houses and courtyards large numbers of larvæ can seldom be obtained. A successful dip may produce half-a-dozen, but even with three or four dips the total catch may only be one or two larvæ. If large numbers are wanted the pools and swamps in open country must be visited. Here they can be bottled at the rate of 100 a minute with ease.

As was mentioned in last year's report it is probable that the local opinion, which credits the introduction of pipe water into the town with an increase in the amount of fever, is correct in its conclusion, though faulty in its premises, since a large number of wells, which were formerly in daily use and were kept clean, are now abandoned to the mosquitos in favour of the more convenient tap in the wall.

Prophylaxis.—Madras contains, more or less, 18,600 wells.

"*Table of used and unused wells by Divisions.*"

Divisions.	Used.	Unused.
1st Division	2,346	84
2nd „	4,121	252
3rd „	2,370	110
4th „	125	38
5th „	1,796	330
6th „	412	131
7th „	3,789	291
8th „	2,256	200
Total	17,215	1,436

Those classified as unused are probably used on occasions. So to exterminate the mosquitos in the thickly populated parts, where wells are their only breeding places, it is obvious that all wells that are not in constant use must be filled up, or otherwise impermeably closed. Great objections are always raised on the score of expense and possible failure of pipe supply when this measure is proposed, even by those who can easily afford it, and should know better ; so, until the supply and distribution of pipe water can be improved and put beyond reproach, it is probable that both anopheles and fever will coexist in Black Town and elsewhere. When the number and position of the unused wells is more accurately known, and such of them as can conveniently be closed have been closed, it will be possible to consider whether it will be worth while to send a tank of kerosine round and oil the surfaces of all the rest at regular intervals at the public cost.

An endeavour was made to ascertain the prevalence of chronic malaria in some of the outlying parts, as well as in the city itself, by examination of the spleens of as many persons as could be induced to submit to it. Of the 1,199 persons examined in representative localities eight adults and two children had enlarged spleens due to malaria = ·8 per cent. of the total.

In order to collect information with regard to certain points in connection with malaria a circular was distributed to some 200 medical practitioners in the city in January, with the request that they would make observations on the lines suggested during the succeeding twelve months, and communicate their results for tabulation. It is hoped that if a fair percentage are kind enough to comply some valuable facts will be obtained.

Through the kindness of medical officers in charge of hospitals films of blood taken from patients admitted as cases of malaria were prepared and sent for examination. As a rule only one specimen from each patient was obtained, and that not always a very good one, which possibly accounts in a large measure for the failure to find parasites in so high a percentage. In three of these cases another organism belonging to the sporozoa was found in the blood films, which raises the suspicion that a certain proportion of the cases of fever that are usually classed as malaria are in reality due, not to the malarial haematozoon, but to other species of sporozoa. This subject has, however, been discussed at greater length elsewhere.

Table of results of examination of Blood Films during November, December, January, February and March.

Source.	Total No. Examined.	Nothing found.	Crescents.	Intra corpuscular Tertian-parasites.	Other Sporozoa.
General Hospital	18	11	—	7	—
Native Infirmary	30	21	2	4	3

Elsewhere	8	7	1	—	—
Total	87	61	8	15	3

The conclusion is forced on us that a disease which has prevailed for centuries over extensive areas cannot be exterminated off hand without enormous expenditure, and measures that to the masses would seem arbitrary and uncalled for. In spite of vaccination small-pox dies hard. Stringent legislation and large annual grants during the past 16 years have resulted only in bringing it under control. Even supposing that the last word about malaria had been said, which is by no means certain, the most sanguine hygienist could scarcely hope to effect much in less than a decade. The lines on which the work of prophylaxis should proceed are already clearly and strongly indicated ; and, in following them, each year should see progressively effective work being carried on, the full benefits of which cannot, however, immediately manifest themselves.

Small-pox.—The total number of deaths registered in 1900 from small-pox was 46 against 34 of the previous year. The incidence on the vaccinated and unvaccinated is shown in the following table :—

	Attacks.	Deaths.	Fatality.
Unvaccinated	87	33	37·93
Said to be vaccinated but no marks	34	6	17·64
Vaccinated	37	7	18·91
Had previous attack of small-pox	1	—	—
Total	159	46	28·93

	Total deaths.	Under 10 years.	10–20.	Over 20.
Unvaccinated	33	20	6	7
Vaccinated	7	5	—	2

Cholera.—As was mentioned in the report for the previous year the city was comparatively free from cholera during the year 1899. Only 23 deaths were attributed to this cause, the last four months of the year being entirely free from the disease. During the year 1900, the year under report, the case was different. There were cases of cholera in the city all the year round with varying degrees of severity at different periods. In January, 3 attacks and 2 deaths were reported. Of these, one was a case removed from a vessel with passengers from Negapatam to Rangoon. The second and third cases were also purely imported cases, the disease appearing within a short time of their arrival in the city from Chithumbaram where cholera was said to be prevailing at the time. No cases occurred in February and March. In the month of April a death from cholera among the convicts of the Penitentiary was reported by the Surgeon in charge, no information however as to the source of infection was given. Four attacks and 4 deaths were reported in the month of May—3 out of the 4 cases being imported. June returned 5 attacks and 5 deaths. Of these one death was directly traceable to infection derived from a previous case—that of Omar Sahib, the cotton merchant from Madura, the victim being his son. Two cases were taken from s.s. *Ethiopia* and *Penticasta* with passengers from Negapatam to Rangoon. The fourth case occurred in the Penitentiary. The fifth case was that of a Eurasian young lady who came to the city two months previous to the attack for her education. This appears to have been a sporadic case originating in the city. So of the 13 cases that occurred till the end of June only 2 cases were among the permanent residents of the city. In July the disease steadily got worse, cases almost unconnected with one another rapidly springing up in different parts of the city—21 attacks and 16 deaths—a larger number than all the previous months of the year put together were reported. With the exception of 4 cases—2 from s.s. *Ethiopia*, one from Negapatam, and one from Sholapur, and one from a village in Chingleput district, all the remainder were cases that sprung up in the city. From these sporadic cases the disease rapidly spread in spite of all efforts to check it, due no doubt to the very favourable seasonal condition of the time, and was epidemic in the city in August, September, and October—302 attacks and 224 deaths, 300 attacks and 234 deaths, and 115 attacks and 94 deaths, occurring respectively in these 3 months. The disease gradually declined from the latter part of October—November returning but 24 attacks and 21 deaths, and December 48 attacks and 31 deaths.

These figures cannot by any means be taken as representing the full number of attacks and deaths within the city for the year 1900—for this can never be known accurately under the conditions now existing in the city. The figures merely show the number of cases that came within the notice of the Sanitary Department. It is more than probable that a large number of deaths registered under "Fever" and "other diseases," especially during the time of the epidemic, was due to this disease. Owing to the great dislike the mass of the population entertain towards precautionary measures, chiefly disinfection, this course was adopted. It is not possible for the Municipality to prevent it. Causes of deaths are not certified by qualified medical practitioners, nor is it possible at present, as the large majority of the population still look up to Barbers, Vydians, and Hakims, for treatment.

The present epidemic, in accordance with what was seen in previous years, commenced about July, steadily increased in severity in August, September, and October, and came down in November and December. That the seasonal condition of the time more than anything else is the influencing agent in the spread of the disease can no longer be doubted. Previous epidemics of cholera in the city have almost without exception occurred at this period of the year.

There was, however, one peculiarity with regard to the present outbreak of cholera in the city. It was the fact of the presence in the city of a large number of homeless, famine stricken, people from villages of various parts of the Presidency affected with scarcity. These poor men and women with their children, in the hope of bettering their condition, flocked in large numbers to the city. Early in July it was found that the shade of large trees in public roads and open plains in the city were made the homes of these people. They wandered about the city the whole day begging, and returned to their shelters in the evenings. There was yet another class who had not quite reached this level. They did some honest work all day and then occupied some pials of houses. That among these two classes the disease was particularly rife is seen from the fact that about a tenth of the total number of cases was among these people. Considering their small number to the population of the city it must be said that the disease made great havoc upon them. There is nothing surprising about this as it is only natural that a set of people whose vitality has been reduced by continued starvation fall but easy victims to

any epidemic disease. But what is interesting about these cases is not their actual increasing the number of deaths as it is of their contributing so largely to the spread of the disease. Instead of each case establishing one centre of infection it established several centres by actually wandering with the disease from place to place. As many of these cases were picked up in a collapsed state no information as to the places occupied before could be obtained, and no disinfection could consequently be done.

The total number of deaths from cholera was 632, giving a ratio 1·3 per 1,000 of the population. Since 1891 only once this number was exceeded, and that was 1898.

Infantile Mortality.—The infantile mortality, *i.e.*, the ratio of deaths under one year to every 1,000 births is generally considered to be a valuable indication of the state of health of a community, having due regard of course for the influence of other factors. Judged by this standard it is seen that Madras compares by no means unfavourably with the other two Presidency towns of recent years, even before the advent of plague. By their own confession the birth statistics of Bombay are admittedly unreliable, and the ratio for 1900, though correct as far as figures go, requires some explanation. The low rates in Calcutta during the years 1889–92 are probably due to the limits of the town having been suddenly extended, while it took some time for the registration system to work regularly in the new districts. Though absolute accuracy cannot be claimed for the Madras rate, yet the probable error is small and under two per cent. Although the ratio of deaths under one year per 1,000 births remained the same as last year, namely, 272 per 1,000, the ratio of deaths under one year, calculated on the total infantile population according to the 1891 census, rose from 363·8 to 411·5 per 1,000 concurrently with the rise in the general death-rate from 38·1 to 46·2.

Vaccination.—The total number of vaccinations performed within the City of Madras during the official year 1900-1901 was 32,571 against 24,959 in 1899-1900, showing an increase of 7,612 cases. The increase was due to the prevalence of small-pox in the city and to the Vaccination of the Natal and Mauritius Emigration coolies.

Out of 32,571 Vaccinations performed 19,312 were males and 13,259 females. Of the total, 26,696 were successful, 2,419 unsuccessful, and 3,456 unknown. The results of 3,456 cases were not ascertained as it was due to the release of the convicts of the Penitentiary undergoing short terms of imprisonment of from 3 to 5 days and to the rejection of the Emigration coolies who, after vaccination, were found physically unfit by the Medical Inspectors.

Under the revised bye-laws passed in February, 1898, 10,552 cases were brought to the Vaccine Depôts for inspection of the result of the operation out of a total of 28,376 cases vaccinated in the Municipal Vaccine Depôts. With the exception of the jail convicts (2,252) the result of 15,572 cases vaccinated were ascertained by the Vaccinators of the respective Divisions, and to minimize prosecutions under bye-law 5 the parents and guardians who failed to produce the vaccinated children for inspection were warned to take them to the Vaccine Depôts for the inspection of the Vaccinator. The result of 2,252 convicts vaccinated in His Majesty's Penitentiary were inspected by the Deputy Inspector of Vaccination during his weekly visits.

Of the total number vaccinated, 1,698 were Europeans, East Indians and Native Christians, 2,070 Muhamadans, 28,798 Hindus, and 5 other castes. Out of 32,571 cases vaccinated, 19,875 were primary vaccinations against 19,082 in the previous year, showing an increase of 793 cases, the increase being due to the vaccination of the Natal and Mauritius Emigration coolies and to the prevalence of small-pox in the city. The percentage of success in primary vaccination was 98·61, showing a decrease of 1 per cent. below the year 1899-1900, and the cause of decrease is attributed to the different kinds of lymph employed in vaccination, viz., calf to arm, glycerinated lymph, and lanoline vaccine paste. The number of re-vaccinations done among the adults was 12,696 against 5,877 in the preceding year, showing an increase of 6,819 cases. The percentage of success in re-vaccination was 78·18, showing an increase of 1·82 per cent. over 1899-1900.

During the year 13,687 infants under one year of age were vaccinated, including those which were done in the Emigration Depôts, against 13,530 in the preceding year, showing an increase of 157 cases. The percentage of success was 99·58 against 99·73 in 1899-1900, showing a small decrease of ·15 per cent. The decrease is due to the low percentage of success obtained in the Emigration Depôts, viz., that out of 78 cases vaccinated under one year from lanoline vaccine paste 68 were reported as successful.

Plague Measures.—During the year plague was indigenous at Vaniyambadi, and there were ten imported cases, against four last year, although the indigenous boundary was further away. Large numbers of Muhamadans left Vaniyambadi and came to Madras to avoid being troubled by the plague precautions there. Enquiry showed that the disease was not prevailing among this community, so their arrival did not give rise to any anxiety. It is not possible to give a more favourable forecast of what the future may bring to Madras than could be given in the two preceding years. No new facts concerning the march of plague epidemics have been recorded, and reason consequently forbids reliance on the comforting though unsupported belief in the antagonistic effect of the climate of Madras on the bacillus of plague.

Sanitary Defects and Sanitary Progress.—The Mylapore drainage system has continued to afford satisfaction. There was but little heavy rain throughout the year, so no complaints were received of flooded courtyards or backing up of sewage. On the other hand complaints from the neighbourhood of St. Thomé High Road were both frequent and forcible. They all referred to unbearable smells at night, the direction of which could not be specified. Every attempt to locate the cause failed, and no assistance could be obtained from the complainants, who were all informed of the address of the Sanitary Inspector, and urged to send and fetch him at whatever hour the smell might be perceived, so that he might have a chance of tracing it to its source. No messages, however, were ever sent to him. Finally, after a number of the ventilating pipes had been raised, more as a sop than in the conviction that they were at fault, the complaints, and, presumably, the smell also, ceased.

A point that must not be lost sight of in the extensions of this system to other parts of Madras is that ventilating tubes, more especially those of small diameter, should lead directly without angles or curves from the point to be ventilated to the open air. In Mylapore it is not unusual to find two right angles in such tubes, and even as many as five right angles in a 1½-inch tube are seen in more than one place. This means, of course, that many of the tubes are utterly useless as ventilators unless there is enough pressure of gas inside the sewer to overcome the friction. When the pressure in the sewer is the same as that of the air, the usual condition, there can be little or no interchange of gases through a narrow tube with four or five right-angled bends.

Wherever this sewerage system is laid down in Madras it will be necessary to keep two gangs of coolies, one to flush and clean out the house connections, and the other to attend to the deposits in the manholes and pipes. Neither house connections nor pipes can be left to look after themselves.

The drainage scheme is slowly progressing. The first two miles of the cast-iron main were laid in the 1st Division, but the work has been stopped for some months owing to a controversy with the Madras Railway. The wells of the Ice House Road pumping station have been sunk and a pipe laid the whole way from there to Mount Road with some side connections. It will be a great advance when the sewage of Royapettah can be carried away down this drain, and its apology for a sewage farm can cease to exist. As the work of pipe laying proceeds the structure of the ground excavated will be noted, so that eventually it will be possible to form a better idea of the surface strata in different parts of the town.

Attention must be drawn to the fact that the present drainage loan does not provide for any alteration in the existing drains of Black Town. This system of side drains, from which apparently so much was expected at its inception some 15 years back, must, after due experience, now be condemned without qualification. No advantages over closed drains with trapped house connections, wherever the latter are applicable, can be claimed for these open side drains, often without proper gradients, whereas space will not admit of even an attempt to enumerate their disadvantages.

Open cemented side drains are only two steps in evolution above the primitive gutter in the earth at the roadside locally known as a "ditch drain." Intermediately in the series is placed the square, leaky, open, brick drain. Together with the defective system of side drains there exists a deficiency in the carrying capacity of at least one of the three large sewers of Black Town, namely, sewer No. 1, which runs the whole length of Popham's Broadway. Whether this sewer was originally made too small, or whether the volume of sewage that now finds its way into it has been largely augmented of recent years by reason of additions to the number of public and private water taps, the fact remains that it is now unable to carry away the sewage sufficiently fast. It will shortly therefore have to be relaid on a larger scale.

The southern outfall of the old main drain is the cause of annual correspondence with the military authorities in Fort St. George. Some eight years ago it was decided to prevent any sewage finding its way into this enormous old drain at any point at ordinary times, and to reserve it for carrying off the overflow and storm water during the rains. It is now found, however, that the main drain has sewage flowing into it at all times, partly from existing openings having been overlooked at the time of the diversion of the sewage mentioned above, partly from surreptitious connections having been subsequently made by adjacent householders, partly from the blockage of the silt traps of the side drains during the night and early morning with leaves and straw, when the side coolies are not on duty to attend to them, and partly from the insufficiency of sewer No. 1. Hardly any of the openings into the main drain are trapped, and the smell given off at various points from it is most offensive. The drain is bound to exist as a storm water channel unless other provisions can be made, but in its present condition it is a most unhealthy adjunct to the sewers, and the percolation from it is liable to contaminate wells in its immediate neighbourhood. Steps are now being taken to remove the silt which has accumulated in it by a rearrangement of the departmental coolies without having recourse to a contract and large expenditure as on previous occasions years ago. Some idea may be formed of the time this is likely to take when it is known that 100 feet of this drain contains from 1,600 to 2,400 cubic feet of solid mud.

A certain amount of water pipe cleaning has been done in the course of the year; besides this nothing particular has been done. Owing to a somewhat severe outbreak of cholera in villages near the Red Hills Tank the question of acquiring a part at least of the catchment area was again freely discussed. A special staff, consisting of a sanitary inspector and peons and coolies, was appointed to aid the permanent conservator and his men in their work of keeping watch over infected villages and preventing fishing and washing of cattle in the tank, while further measures were taken by the Collector of Chingleput. The channel to Kilpauk also claimed attention. It may be here pointed out that, since the scheme for the improvement of the water supply is a comprehensive one, and will cost many lakhs, it will not be possible to carry it to a conclusion for many years. It is only reasonable, therefore, that the most important part of the scheme, that is, the part which will have the greatest influence in improving the quality of the water, and reference to the Chemical Examiner's analyses and former reports will show how necessary that improvement is, should be undertaken first of all. It is self-evident that the nearer to the taps contamination of a water supply occurs the less chance exists of self purification and the greater the likelihood of evil effects following upon the use of the water. Therefore, instead of spending money in acquiring a catchment basin twelve miles away, it would be a sounder policy to commence the work at the nearest point, namely Kilpauk, and erect some species of filter. When funds allow, extensions can be made further afield by covering in the channel, or laying a masonry aqueduct, and, finally, completing the scheme by acquiring the catchment area. The only permissible deviation from this order of procedure would be to temporarily fence the channel with barbed wire or otherwise if there appears to be no possibility of obtaining funds for the larger and more radical work of filtration for many years.

LIBRARY OF THE BOMBAY BRANCH OF THE ROYAL ASIATIC SOCIETY

ABSTRACT OF THE REPORT OF THE ACTING MUNICIPAL COMMISSIONER OF BOMBAY CITY FOR 1900-1901.

(*W. D. Sheppard, Esq.*)

Public Works.

Special Drainage.—The Special Drainage Department was placed under the Executive Engineer as a branch of his department. The works executed or under execution in the Special Drainage Branch during the year included the ovoiding and constructing of masonry side drains and the construction of storm-water drains in various parts of the city, the improvement of roadside drains and water courses in and about Dadar Road, the erection of machinery for various Sectional Sewerage Works, the construction of the Mazagon Sectional Sewerage Works, the Fergusson Road and Chinchpokly Sewerage Works, and the Parel Sectional Sewerage Works. During the year the Corporation, after obtaining the opinion of the late eminent sanitary engineer, Mr. Santo Crimp, sanctioned the construction of certain works, costing in the aggregate about £90,000 for the drainage of the lower parts of the city. The scheme involves the cutting off of all tidal communication from Mahim Bay at a certain point, and Government are about to undertake legislation extinguishing all tidal rights and rights of navigation at that point. When the Act is passed it will be possible to proceed with the works.

Pumping Station at Love Grove, Worlee.—The engines and pumps worked satisfactorily during the year. There was a stoppage of the pumps for about seven hours on the early morning of the 26th July, 1900. This was immediately remedied. The efficiency of the pumps as tested by monthly observations showed an average of 88·58 per cent.

House Connections.—The street portions of house drainage connections carried out by the contractors numbered 6,002 at a cost of about £9,000.

Water Works.—*Tansa Lake.*—The rainfall for 1900 was 104·60 inches against 40·07 inches for 1899. Owing to the early cessation of the rain the lake fell to 391·6 T. H. D., the lowest level on record. The total quantity of water received in the lake was 41,888 million gallons, or 52 per cent. of the rainfall on the catchment area of 52·5 square miles. A large number of old trees, which had been left in the lake when it was constructed, were cut down and removed at the end of the hot weather when the level of the lake was at its lowest. On the night of the 18th February, 1901, a portion of the Tansa duct gave way. The repairs were executed by the evening of the 28th, and water was turned on again in the duct on the 1st March. One burst on the 48-inch pipe necessitated the water being shut off for nearly 36 hours.

Vehar Lake.—The rainfall for 1900 was 72·96 inches against 35·26 inches for 1899. The total quantity of rain which fell in the whole drainage area of 3,900 acres was about 6,450 million gallons, of which about 4,650 million gallons reached the lake or 72 per cent. of the total rainfall. The margin of the lake was thoroughly cleared of weeds which were rooted out as the water receded.

Tulsi Lake.—The rainfall for 1900 was 93·02 inches against 43·80 inches for 1899. The total quantity of rainfall on the whole drainage area of 1,700 acres was about 3,602 million gallons, of which about 2,778 million gallons reached the lake, or about 77 per cent. of the total rainfall.

Supply and Distribution, &c.—There were 135 bursts in several mains. 379 new connections were made and 189 connections were cut off for various reasons. The total number of connections is 20,394.

Public Health.—The state of the public health during the year was not satisfactory, the total mortality, exclusive of still-born, being 79,350. This mortality is the highest ever recorded for the city.

There were 13,285 deaths from plague, against 15,796 during the previous year. Plague measures have been carried out as before by a separate branch of administration.

On an average 6,862 men and women and 1,188 scavenging and drain carts, and 204 night-soil and cesspool carts were at work each day. 348,152 tons of garbage, equal to 953·84 tons a day were collected, removed and disposed of against 344,268·5 tons of garbage in the preceding year. 172,459·83 tons of night-soil and cesspool matter, equal to 473·04 tons a day were collected and removed against 170,506·11 in the previous year. 202 miles of covered drains were opened and cleaned against 167·1 miles in 1899.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF BOMBAY CITY FOR 1900.

(*J. A. Turner, Esq., M.B., D.P.H.*)

Population.—The population of Bombay City, estimated by the Census of 1891, was 821,764, and it is on this population that the statistics for 1900 are based.

Births.—The number of births registered was 12,688, giving a birth-rate of 15·43 per 1,000 of population. Owing to the faulty system of birth registration these figures are unreliable. Owing also to the migratory habits of a certain class of the population a proper register of births has hitherto not been available.

The abnormally low birth-rate can be accounted for in many ways :—

1. The proportion of males to females 170·60 to 100.
2. The mother often leaves the city before the child is born, and this birth is not registered when she returns.
3. The occupation of the mother entailing hard manual labour under very indifferent conditions must have a very deleterious effect on the birth-rate.
4. Famine and plague have direct influence on the marriage-rate, and consequently on birth-rate.

The number of the births registered was, however, 2,064 more than last year. Of the total number of births 6,552 were males and 6,136 females ; 2,062 still-born births were also registered during the year under report. Birth-rate amongst Parsees and Europeans is little higher than in the previous year.

Deaths.—The number of deaths in the City of Bombay during 1900, exclusive of still-born, was 79,350, giving an annual death-rate of 96·56 per 1,000 of the population. This mortality is the highest ever recorded in this city.

The death-rate from all causes during the past 10 years was.:—

Years.	Death-rate.	Years.	Death-rate.
1890	25·35	1895	30·52
1891	29·01	1896	40·71
1892	32·26	1897	58·28
1893	28·16	1898	63·23
1894	53·25	1899	68·07

Mortality from Zymotic Diseases.—The principal zymotic diseases, under the heading of which deaths are returned in Bombay, are Plague, Cholera, Small-pox, Measles, Ague, Enteric Fever, Puerperal Fever, Relapsing Fever, Remittent Fever and Malaria. The number of deaths from zymotic diseases was 34,998, giving a zymotic death-rate of 42·58 per 1,000 of the population.

TABLE SHOWING THE NUMBER OF DEATHS AND THE DEATH-RATE FROM DIFFERENT CAUSES IN 1900.

Cause of Death.	No. of Deaths.	Death-rate per 1,000 of Population.
Small-pox	3,018	3·67
Measles	1,500	1·82
Fevers	7,928	9·64
Cholera	4,273	5·19
Plague	13,285	16·16
Phthisis	8,199	9·97
Diseases of the Nervous System	4,328	5·26
Do. Respiratory System	12,522	15·23
Diarrhœa	5,850	7·11
Dysentery	2,826	3·45
Accidents	1,072	1·30
All other Causes except Still-born	14,549	17·70
Total	79,350	96·56

Plague.—During the year the control of all plague measures was under Government. The Municipal Commissioner with his personal assistant and officers of the army, were appointed to carry out the measures for the control of plague. Under these officers were appointed a number of medical men and subordinate staff to carry out the only measures enforced; namely, disinfection by washing the floors and walls of infected houses with a solution of perchloride of mercury 1 in 1,000 parts. Evacuation of infected houses, and removal to hospital was not enforced. The returns available show that there were 17,913 attacks and 13,285 deaths from the plague. In 1899 there were 19,051 attacks and 15,796 deaths.

Total mortality.—45,429 males and 33,921 females died during the year; excluding those under five years, the highest number of deaths amongst males occurred in the age-period between 25 and 29 years, 4,789 deaths having been registered; and amongst females, 4,709 in the age-period of 60 and over.

Amongst persons born in Bombay 18,524 deaths were registered during the year and amongst those born outside of Bombay 57,977.

It is noticeable that the low caste Hindus, excepting negro Africans, Buddhists and Lingaets who form very small communities, show the highest mortality, *viz.*, 214·57 per 1,000 of population. The Jain community, which includes Banias, also suffered much, their death-rate being 95·73. Mussulman give a death-rate of 102·57, and the general mass of the Hindus give a death-rate of 97·12, the death-rate amongst Parsis was 37·63. European death-rate being little higher than in the previous year.

Small-pox.—This disease was very prevalent during the early part of 1900, 3,729 attacks and 3,018 deaths occurring. This gives an increase of 2,578 deaths over last year, and 2,714 more than the average of previous five years. As in other diseases Hindus of other caste suffered the most, Hindus low caste and Mussulmans being the next. There were 16 deaths amongst Europeans. The disease was practically confined to children under one year of age.

Cholera.—There was a serious epidemic of cholera during the year, 4,815 attacks and 4,273 deaths being registered, against 111 deaths in 1899. The

disease began in January (1–1–1900) and continued until December (28–12–1900). Strict precautions were taken to prevent the disease spreading. The highest number of deaths from this disease were registered in the month of August. Amongst sections Byculla had the greater number of deaths from cholera. Of the total number of deaths 2,948 occurred amongst Hindus of other castes and 628 amongst Hindus low caste. A total of 332 deaths occurred amongst persons who had resided in Bombay for three months and under and 445 deaths occurred amongst persons who resided in Bombay for six months. The great number of deaths occurred in persons born outside of Bombay.

Fevers.—A total of 7,928 deaths was registered from fevers. Remittent fever claims the highest number, viz., 7,278, being 2,517 more than the last year and 1,913 more than the average of the previous five years. To simple continued fever 45 deaths were ascribed, being 99 less than the last year and 611 less than the average. To enteric fever 60 deaths were put down, being 16 more than the last year and 23 more than the average of the last five years. To ague 545 deaths were ascribed, being 431 more than the last year and 342 more than the average. Out of the large number of deaths returned as due to remittent fever, many may have been due to relapsing fever and plague, as it is very difficult to diagnose the disease without strict examination being held in each case. The fever mortality rose and fell with the mortality from plague. It rose from January to March, when 1,166 deaths were registered. The highest number of plague deaths registered in the month of March was 3,125. From the month of April fevers gradually decreased till the end of the year. Amongst the Hindus of low-caste there was a considerable increase, the rate being 22·18 as against 14·61 in the previous year. There was also an increase amongst the Hindu community and Mussulmans. Parsees showed a slight increase and the Europeans a slight decline. Dongree, Byculla, Parel, and Mahim sections give the highest incidence of fever mortality.

Measles.—From measles 1,500 deaths were registered from this disease, being 368 less than in the last year, and 847 more than the average of the preceding five years. Great number of deaths occurred amongst Hindus of other caste. The Hindus low-caste give the highest death-rate. The infant mortality, due to measles, was high and the age-period under two years was the most fatal. The female death-rate from this disease was little higher than that of males.

Phthisis.—From phthisis 8,199 deaths were reported, being 2,170 more than in the previous year. It is difficult to say how far these figures are correct as a very small percentage of the deaths were certified by medical practitioners. Other diseases of the respiratory system amount to 12,522 deaths under the heading of bronchitis, pneumonia, pleurisy, &c.

General.—From diseases of the digestive system 10,504 deaths were registered, being 4,945 more than in the previous year and 6,419 more than the average. Diarrhœa and dysentery show a very marked increase both as against last year and on the average. To diseases of the nervous system 4,328 deaths were registered, being 1,316 more than the last year and 2,919 more than the average. 12,522 deaths were ascribed to diseases of the respiratory system, being 3,872 more than in the last year and 5,557 more than the average. To diseases of the circulatory system 348 deaths were registered, being five more than the last year and 89 more than the average.

APPENDIX

No. 1.

MEMORANDUM by the ARMY SANITARY COMMISSION on the REPORT of the SANITARY COMMISSIONER with the GOVERNMENT of INDIA for 1900.

The Report is shorter than its predecessor. Whilst the latter covered 244 pages, the present is limited to 139. The number of returns accompanying the report has likewise undergone reduction. It is a pity that it should have been found necessary to omit Tables XIV. and XXXIX., giving "Statistics of Regiments." By means of these two tables the health statistics of, and the stations occupied by, each corps, European and Native, during the year could be ascertained at a glance. They took up a good deal of space, 33 pages between them; and this doubtless suggested their suppression.

2. Like the preceding year, that under report was one of abnormally high temperature; April and October were the only two months in which temperatures about normal were recorded. The excess of heat was greatest in February and March. The rainfall, for India as a whole, was approximately normal. But such a general statement regarding rainfall has to be taken only for what it is worth. Although the rainfall recorded for India, as a whole, might be approximately normal, inquiry would show that its distribution was irregular, one part suffering from excess and another from defect; and, moreover, that the fall, though locally normal in quantity, might be unseasonable. That the climatic conditions of the year exercised an important influence on the course of the destructive epidemics of cholera, small-pox, and fever may be assumed; but, in spite of increasing knowledge of the causation of disease in some special directions, much still remains obscure regarding the relationship which is believed to exist between epidemics and meteorological conditions.

3. The average annual strength of the European Army of India decreased from 67,697 in the previous year, to 60,553 in the year under review. The returns show that, whilst the rate of admissions into hospital and the constantly sick rate were slightly below those for the preceding year, the death and invaliding rates were considerably higher. The ratio of deaths, per thousand of the average strength, which had been 12·75 in 1899, rose to 14·62 in the year under report; whilst the ratio of invaliding which had been 31·64, rose to 33·46. The two chief causes of admissions were, as usual, ague and venereal disease; the former being credited with 27 and the latter with 26 per cent. of the total number from all causes. These figures show that ague was much more prevalent, and venereal disease considerably less prevalent, than in the preceding year. Between them, they were accountable for 53·05 per cent. of all the admissions, as compared with 47·76 in 1899. Whilst the admissions due to ague increased from 235·2 to 308·5 per thousand of strength, those due to venereal disease fell from 313·4 to 298·1. The two chief causes of death were, again, enteric fever and hepatic abscess; whilst the former accounted for 33 per cent. of all the deaths, the latter accounted for 11 per cent. These figures show a reduction in the percentage of deaths due to enteric fever from 40 in the previous year to 33 in the year under review; and an increase from 10 to 11 in the percentage of deaths due to hepatic abscess. With a percentage of total deaths in the Army of 9·9, cholera was little behind hepatic abscess as a cause of mortality. Between them, these three diseases accounted for 53·3 per cent. of the total mortality for the year. As a cause of invaliding, secondary syphilis, again, took the foremost place, followed, but at long intervals, by debility and intermittent fever. Together, these three diseases caused 735 out of a total of 2,026 invalidings from all causes.

4. Of the four Commands, Madras and Bombay were the most unhealthy, the former recording the highest constantly sick and admission rates, and the latter the highest death-rate. The Punjab, which in the previous year recorded the highest death-rate now records the lowest. As usual, the incidence of enteric fever is an important factor in determining the relative mortality in the several commands and stations. To the death-rate of the Bombay Command enteric fever contributed 6·71 of its total of 17·08 from all causes; and to that of Madras 4·71 of 16·53. The Punjab and Bengal Commands, with the lowest death-rates from all causes, had also the lowest death-rates from enteric fever; the former recording from this disease a death-rate of 4·35 out of its total from all causes of 12·62, and the latter of 3·64 out of 13·40. Comparing the geographical groups it is shown that the decennial admission rate from cholera was highest in the Gangetic Plain, and the decennial admission rate from enteric fever highest in the hills. The Indus Valley recorded the highest admission rates from ague and also from pneumonia; whilst the Orissa group recorded, as hitherto, the highest from dysentery. No doubt, a general indication of the healthiness or unhealthiness of the several Commands, Geographical Groups, and Stations, may be gathered from the records of their admission and death-rates during a series of years; but the influence which special conditions affecting the troops may have on these records cannot be left out of count. The ages of the men, their length of service in India, their previous exposure on field service, or in camp during epidemics, might all have effects on the statistics of sickness and mortality furnished by the several geographical groups or stations. If estimated solely by the returns of sickness and mortality amongst the troops forming its garrison, without taking into account such special conditions as those mentioned, a station might appear to be healthy during certain years and unhealthy during others, whilst its sanitary state, so far as could be determined by investigation, continued the same or had improved.

5. The returns of the previous year recorded a single death from each of the three diseases, *cholera*, *influenza*, and *small-pox*. During the year under report there were 88 deaths from cholera, none from influenza, and three from small-pox. In a year when cholera prevailed with exceptional severity amongst the people of India, it was not to be expected that the troops stationed in their midst would escape. In British India alone, nearly 800,000 deaths from cholera were registered; and it is certain that there were many more which escaped registration. During the two preceding years, 1898 and 1899, the disease was in remarkable abeyance in India, and the mortality due to it the lowest on record. Accompanying this comparative freedom of the general population from cholera during those two years, the European Army enjoyed a corresponding immunity, only 14 deaths having been caused by it in the former of the two, and only one in the latter. Its recrudescence in wide-spread epidemic form amongst the general population in the year under review was accompanied by its increased prevalence amongst the troops, European and Native. That the death-rate from cholera in the European Army did not exceed 1·45, per 1,000 of strength, whilst amongst the general population it rose to 3·7 may be taken to indicate the better sanitary conditions under which the former, as compared with the latter, met the epidemic.

6. *Ague* was more prevalent and fatal in the European Army than it had been in the previous year. As with cholera and small-pox, increased mortality from ague in the European Army accompanied increased mortality from ague in the general population. The deaths ascribed to this cause amongst the latter increased by nearly 19 per cent. Excess of rainfall and the floods therefrom resulting are mostly assigned as the causes of this increase. The Report deals at considerable length with the recent researches into the causation and distribution of malarial fevers. The part which mosquitos play in connection with these fevers is being closely studied by numerous investigators in various parts of the world. It is confidently predicted by the more sanguine that the application of the knowledge now being acquired to the prevention of these diseases will lead, if not to their entire disappearance, at least to a marked decrease in their prevalence. The methods hitherto found to be the most effectual in preventing and curing malarial fevers do not appear likely to lose any of their importance as a consequence of recent discoveries. On the contrary, it seems probable that drainage and the use of quinine may in future have more value than ever assigned to them in the combat with these diseases. The mode of action of drainage and quinine on malarial fevers has hitherto been imperfectly understood. The tendency of the researches in progress seems to be towards an elucidation of their mode of action, and to showing that their application rests on a scientific basis.

7. The death-rate from *enteric fever*, which had been 10·17 per 1,000 of strength in 1898, decreased to 5·14 in 1899, and now in the year under report to 4·77. Lessened influx of drafts from England and less field service, the causes to which the diminution of the disease during the preceding year was ascribed, continued also throughout the year under report. No such connection as that shown to exist between the rise and fall in the prevalence and mortality from cholera, small-pox, and malarial fevers among the general population, and their rise and fall amongst the European troops, can be traced in the case of enteric fever. Reliable statistics of the prevalence of the disease amongst the natives of India are mostly limited to those furnished by the Native Army and jails. Whilst the recorded deaths from enteric fever numbered 289 out of a strength of 60,553 European soldiers, there were only 18 in the Native Army with rather more than double the strength, and only 17 out of an average strength of 121,511 prisoners. As in previous reports, a *résumé* is given of the latest additions to the literature of enteric fever. The same conflict of opinion regarding the question of the media by means of which infection is communicated, prevails amongst those who write on the subject; a diminishing number claiming that the disease is "solely water-borne," some blaming flies and others dust for diffusing infection. Amidst much that is still undecided and obscure, the records of sickness and mortality support the conclusion that young soldiers of the ages of from 20 to 25 years, and those in the first year of their residence in India are the most liable to contract and die from enteric fever.

8. The prevalence of *venereal disease* has continued uninterruptedly to decrease since 1895, during which year the admission-rate due to it had attained its maximum of 522·3, per 1,000 of strength. The admission-rate for the year under report was 298·1. Although only 14 deaths were attributed to venereal disease during the year, the sickness and invaliding caused by it were greater than those caused by any other disease. As in the case of enteric fever, part of the decrease in the prevalence of venereal disease is attributed to there having been fewer drafts of young soldiers. So far, the measures adopted during recent years with the object of lessening the disastrous effects of this scourge have been productive of marked benefit; but the returns show that there is still ample room for further reduction of the numbers rendered inefficient by it.

9 The average strength of the *Native Army* was 123,463, or less than in the preceding year by 5,066. There was a considerable increase in the rate of admissions into hospital, and a very great increase in the death-rate. To greater prevalence of ague the increase of the admission-rate was mainly due; whilst cholera was chiefly responsible for the marked rise in the death-rate. This last, which had been only 10·70, per 1,000 of strength, in the preceding year, rose to 14·04 in the year under report. Pneumonia caused nearly 24 per cent. of the total deaths from all causes, and cholera over 22 per cent. Of the four Commands, Bombay was much the most unhealthy, returning a death-rate of 18·71, per 1,000 of strength, against the next highest of 14·72 in the Punjab. This high rate of mortality in the Native Army in the Bombay Command was synchronous with the prevalence of excessive sickness and mortality amongst the general population of the Bombay Presidency; the death-rate for which latter was 70·07, the highest on record.

10. Whilst *influenza* was less prevalent than in any year since the disease invaded India in 1890, *cholera* was unusually prevalent and fatal. The most important outbreak of cholera, that which occurred at Kohat, was traced, it was believed, to the use by the troops affected, of polluted drinking water. An inquiry into the causes of the outbreak by the medical officers on the spot appears to have led them to this conclusion. But the evidence in its support is not altogether complete. "It is not known how the irrigation water became infected, but the disease was at the time spreading

epidemically in the Punjab, and the first reported death in Kohat city was reported on the 5th July," the day before the regiment which suffered most marched into the place. "The men of the 6th Punjaub Infantry and other regiments are also supposed to have drunk the polluted irrigation water, because it was so much cooler than the pipe water." The morbific agent of cholera does not appear to have been detected in the water, although "the ready detection of spirilla and allied forms was considered sufficiently confirmative of the suspicion attaching to the stream."

11. *Malarial fevers* were more prevalent in the Native Army than during the previous year, as they likewise were amongst the general population: but the mortality due to them did not widely differ in the two years. The combined death-rate from intermittent and remittent fevers amounted to 1·85 per 1,000 of strength, in 1899, and to 2·27 in the year under review. There was, however, a marked increase in the number of cases attributed to *enteric fever*. In the whole Native Army, 54 cases with 18 deaths were returned, as against 18 cases with three deaths in the preceding year. The increase of enteric fever in the Native Army represented by these figures, during a year when there was a considerable decrease in its prevalence and fatality in the European Army, is not a little remarkable. It appears that whilst 16 regiments were contributors to the total number of 54 cases in the Native Army, one regiment, the 42nd Gurkhas, had no fewer than 29 admissions from this disease. In last year's Report we find the following remark regarding the prevalence of enteric fever in the Native Army :—"It may be worth mentioning that year by year one medical officer's diagnosis contributes a considerable proportion of the cases registered in the Native Army." The remark applies to one, although perhaps not to the same, medical officer during the year under report.

12. Along with increased prevalence of *small-pox* amongst the general population, the admission and death-rates from this disease in the Native Army showed a corresponding increase. The admissions numbered 78 and the deaths four. There were 56 cases of *plague* with 29 deaths. "The comparative immunity of the sepoys as compared with the populations surrounding them is ascribed to the large number of men inoculated, many of them twice, and to the immediate segregation of patients and evacution of buildings whenever cases did occur."

13. *Tubercle of the lungs* shows some increase in prevalence and fatality in the Native Army. Gurkhas are the chief sufferers from this disease; the five highest numbers of cases having all been in Gurkha regiments. In one of those regiments the Medical Officer attributes the increase of pulmonary phthisis "to the overcrowding, associated with small cubic and superficial space per man in the barracks." The Sanitary Commissioner remarks that if the prevalence of the disease among the Gurkha soldiers is not due to any special racial liability, and of this nothing is said by the medical officers, but is the result of defective sanitation, "it is high time that something was done to prevent waste of life among these valuable soldiers."

14. Although the mortality due to it was somewhat below that of the previous year, *pneumonia* was, as usual, the most fatal disease in the Native Army. It is probable that the slight decrease in the prevalence of the disease may have been due to there having been less influenza, of which disease it is a not infrequent concomitant or sequel.

15. The ratio of admissions from *venereal disease* increased from 34·1 per mille of strength in the previous year to 42·5 in the year under report. There were nine deaths and 129 invalidings directly due to it. The disease is thus seen to be by no means an unimportant cause of inefficiency in the Native Army, although its injurious effects seem inconsiderable when compared with those produced by it in the European Army. In the parts of the country which suffered most from famine, an unusual number of destitute women resorted, it is said, to prostitution; and to this cause the increase in the prevalence of venereal disease in some regiments is attributed by the medical officers.

16. The average strength of the *Jail* population of India closely approximated to that of the Native Army. The ratios of sickness and mortality amongst the prisoners were, however, far higher than those which prevailed amongst the native soldiers. Whilst among the latter the admission rate, per thousand of strength, was 784·6, amongst prisoners it was 976·6. Their death-rates differed yet more widely, the Native Army recording a death-rate of 14·04 against one of 34·2 by the jails. In jails, bowel-complaints were, as usual, the diseases most destructive to life. Between them, *diarrhœa* and *dysentery* caused 28 per cent. of the total jail mortality; in the Native Army the same diseases accounted only for 6·6 of the total mortality. It was only to be expected that the prisoners would suffer more from *tubercle of the lungs* and *pneumonia* than the Native troops. Whilst the former record a death-rate from these two diseases combined of 8·17, the latter record a death-rate from them of only 4·10. In other words, the troops, who pass more of their time than the prisoners in the open air, had about half the mortality from lung diseases recorded by the latter. From *cholera* the death-rate was high, both in the Native Army and in the jails, but considerably higher in the former than in the latter, a result perhaps due to the facilities for isolating prisoners at a time when the general population was suffering from the disease. The ratio of mortality from *enteric fever* was almost the same amongst prisoners and native soldiers, having been ·14 per thousand of strength for prisoners and ·15 for native soldiers. *Cerebrospinal fever*, hitherto an inconsiderable factor in the production of sickness and mortality in Indian jails, caused no fewer than 99 admissions with 79 deaths during the year under report. As observed by the Sanitary Commissioner with the Government of India, in his concluding remarks on the jails :—"The heads of jail mortality requiring special attention are bowel complaints, tubercle of the lungs, and respiratory diseases."

17. The remaining sections of the Report deal with the statistics and chief diseases of the general population, vaccination, and sanitary works; but as these subjects have been noticed in our Memoranda on the several Provincial Sanitary Reports they need not be again referred to here.

18. *Summary.*—The Report has been greatly reduced in length, and some of the tables of statistics which formerly accompanied it have been omitted. Amongst the latter, Tables XIV. and XXXIX. gave much useful information regarding the European and Native Armies. The meteorological features of the year did not widely diverge from normal, except that temperatures were higher than

usual in all of the months except two. Measured by the death and invaliding rates, the health of the European Army was not so good as in the previous year. The chief causes of admissions into hospital continued, as heretofore, to be ague and venereal disease; and the chief causes of death, enteric fever and abscess of the liver. The Madras and Bombay Commands were the most unhealthy; whilst the Punjab Command, which in the previous year recorded the highest death-rate, returned the lowest for the year under review. Cholera, which prevailed in severe epidemic form amongst the general population, caused considerable mortality in the European and heavy mortality in the Native Army. Ague was more prevalent than in the preceding year; whilst enteric fever was decidedly less prevalent and fatal—a result due in main part, it is believed, to lessened influx of drafts of young soldiers from Europe. Accompanying this decrease of the prevalence of the disease in the European Army, there was a marked increase in the number of the admissions and deaths attributed to it in the Native Army. A single regiment contributed more cases than all the rest of the Native Army together. Venereal disease shows a further decline, but still accounts for an admission rate of 298·1, amongst the European troops. In the Native Army there has been not only no decrease, but a considerable increase; the admission rate does not, however, exceed 42·5 per thousand of strength. Accompanying unusual sickness and mortality amongst the general population there was a marked increase in the admission and death-rates in the Native Army. A violent and fatal outbreak of cholera took place among the native troops at Kohat. Lung diseases are still the cause of much sickness and mortality in the Native Army, and especially among the Gurkha soldiers, suggesting the need for improving the ventilation of their quarters. Of the Jails of India the Sanitary Commissioner observes:—"The heads of jail mortality requiring special attention are bowel complaints, tubercle of the lungs, and respiratory diseases."

No. 2.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bengal for 1900.

The Report, with the Appendices, is of less than half the length of its predecessors. Yet, according to the estimate of its value expressed in the Government review, "its utility is unimpaired." In the Government review itself, however, comment is made on the meagreness of the account given of *plague*. Endeavour on the part of the Sanitary Commissioner to throw "light on the origin of the disease, the causes which foster or retard its spread, or the success or failure of the measures adopted to check it" would probably have been found to be fruitless without exceeding the limits prescribed for the length of the Report. A similar comment might have been applied to the account given of the most destructive epidemic of cholera which has visited Bengal since the introduction of registration of vital statistics. Brevity is a commendable feature of the Report, but it is not without its drawbacks.

2. The year was an unhealthy one. The rainfall, which the Sanitary Commissioner considers to have an important influence on the health of the people, was, on the whole, considerably in defect, and also very irregularly distributed. It was generally scanty in the earlier months of the year, the monsoon was late in commencing, and the last two months were almost rainless over the greater part of the Province. These conditions are considered to have been not only unfavourable to the agricultural outturn, but to have been prejudicial to the public health. The mortality from all of the chief diseases exceeded that of the previous year.

3. Whilst the *death-rate* rose from 31·21 in the previous year to 36·63 in the year under review, the *birth-rate* fell from 42·96 to 38·68. The increase in the former was "chiefly due to the greater unhealthiness of the year under report as evidenced in the severe and widespread prevalence of fever and cholera throughout the Province." The high price of food grains during the greater part of the year was also, doubtless, a contributory cause to decreased fecundity and increased mortality. It is satisfactory to learn from the 7th paragraph of the Report that the measures which have proved so successful in improving the registration of vital statistics during recent years are being stringently enforced. The verification by vaccination officers of the entries of births and deaths shows that a considerable number of both still escape registration. In Bengal, as in other provinces of India, the difficulty is, and for years to come will doubtless continue to be, to secure a reliable record of the causes of death. Including, as it does, in its population a large number of qualified medical men, European and Native, it may be assumed that Calcutta furnishes a more accurate return of the causes of death than the rest of the Province. Comparing the returns of death, according to their causes, for Calcutta with those for Bengal towns, and for districts excluding towns, it is manifest that, whilst with regard to such causes as *injury* and *cholera*, which are recognised even by the most uneducated, the rates per thousand do not widely differ, it is much otherwise in the case of *fever*, *diarrhœa* and *dysentery*, and *other causes*. In Calcutta the death-rate ascribed to fever during the year under review was 11·21 per thousand of population; in the other towns almost exactly double; and in districts, excluding towns, 24·17. Likewise, the death-rate ascribed to diarrhœa and dysentery in Calcutta was 6·05, and in the other towns 3·50; whilst in districts it was only ·75. On the other hand, whilst Calcutta attributes to "other causes" a death-rate of 30·47, Bengal towns record under the same heading a rate of only 8·92; and districts, exclusive of towns, 5·78. If, for the reasons stated, the Calcutta returns be accepted as affording an approximately accurate record of deaths according to their causes, those for Bengal towns and districts, more particularly as regards such causes as fever and bowel complaints, differ from them so widely that they cannot be accepted as furnishing anything like a reliable measure of the real mortality from these diseases.

4. *Chief Diseases.*—The mortality from *cholera* was the highest on record in the Province since the introduction of the present system of registration of vital statistics. The excessive prevalence of the disease is attributed to opposite climatic conditions : early cessation of the rains in the previous year, followed by the absence of spring rain in the year under review, "brought about conditions favourable to cholera," whilst the abnormal rainfall in some districts during September washed the poorer people out of their houses, and polluted the water supplies accessible to them. And again, "The early cessation of the rains of 1900, and the consequent early subsidence of the rivers, led to a heavy mortality from cholera in most of the districts of Eastern Bengal." No doubt the conditions described and excessive cholera-prevalence co-existed, but evidence to show that the latter was due to the former is wanting. The endeavour to disinfect wells by means of the permanganate of potash created a panic in some places; the people, it is stated, forsook the disinfected wells and took to dirty puddles instead. Sanitary officers are not yet unanimous as to the effect on cholera of disinfecting the wells with permanganate of potash. The question can only be definitely settled by a series of experiments conducted on scientific principles, as suggested in the Government review of the Punjab Sanitary Report for 1895. Anti-cholera inoculation would appear to have been remarkably successful in conferring immunity from attack. Out of 1,527 coolie emigrants who were not inoculated at Goalundo, 32, or 2·09 per cent., got the disease ; whilst out of 873 who were inoculated, only two, or ·22 per cent., suffered from it. If these figures represent the degree of protection which anti-cholera inoculation is capable of conferring on those who undergo it, the expediency of inoculating all coolies before despatch to the Assam tea gardens can hardly be a matter of doubt.

5. A death-rate from small-pox of ·29 per thousand of population, though higher than that for the previous year, and higher than the average for the past ten years, cannot be regarded as excessive for the Province as a whole. But in certain districts, such as Cuttack, the death-rate was very high. The inhabitants of the Orissa Division, of which Cuttack is a district, still prefer inoculation to vaccination. Inoculation, which is practised chiefly among the well-to-do classes, keeps alight and diffuses small-pox contagion amongst those unprotected by vaccination, inoculation, or a previous attack of small-pox. The remedy would be to place vaccination within the reach of all, and to suppress inoculation. Vaccination made good progress during 1900–01 ; the number of operations exceeding the number in the preceding year by 93,730, and the percentage of successful cases having been slightly higher in primary vaccination, and considerably higher in re-vaccination. But, as an indication of how much remains to be done before Bengal can be regarded as a well-vaccinated province, it is only necessary to state that, of 3,117,036 infants under one year of age estimated to have been available for vaccination in the year under report, only 589,376, or less than one out of every five, were successfully vaccinated. Human lymph is still chiefly employed in Bengal, but fresh calf lymph, and lymph preserved with lanoline, are also used to a considerable extent. The results show that fresh calf and humanised vaccine lymphs give nearly the same percentage of successful cases, whilst lanoline lymph gives a much lower percentage of success than either of the other two kinds.

6. The death-rate from *fever* was slightly higher than that recorded for the previous year, and considerably higher than the average rate for the past ten years. Accompanying the increased mortality from fever, there was no corresponding increase, but, on the contrary, a slight decrease, in the quality of quinine sold.

7. The recorded number of deaths from *diarrhœa* and *dysentery* represents almost certainly only a fraction of the actual number. In places like Darjeeling and Calcutta, which return the highest death-rates from these diseases, there is doubtless a more intelligent differentiation of the causes of death than in the districts of Rajshai and Jessore, which return the lowest rates. The death-rates from bowel complaints in the two former districts were 6·33 and 6·05 respectively ; and in the two latter districts only ·05 and ·04 respectively, per thousand of population. The latter figures are obviously worthless except as indicating the backwardness of registration of deaths according to their causes.

8. The deaths recorded under the heading "other causes" have much increased during the past two years, as they have likewise been shown to have increased in the Bombay Presidency since *plague* began to appear there towards the end of 1896. The Sanitary Commissioner states his belief that "plague deaths are generally returned under this head and so to have swelled the death-rate attributed to 'other causes.'" The returns for the year show that, including the figures for Calcutta, the seizures from plague numbered 40,294 and the deaths 38,412. But, taking into account the Sanitary Commissioner's statement above quoted, much confidence need not be placed in the accuracy of these figures. Perhaps the most hopeful circumstance noted in connection with plague in Bengal is the growing tendency of the people to voluntarily adopt measures to protect themselves against infection.

9. *Sanitary Works.*—Various projects were referred to the Sanitary Board during the year with the object of improving the water-supplies and drainage of towns. Of these the most important was the scheme for a combined water-supply to the riparian municipalities.

10. *Summary.*—The Report has the merit of of brevity and also some of its defects. The year was unhealthy. The mortality from all of the chief diseases was greater than in the previous year, and greater than the average of the past ten years. High prices of food influenced both the birth and death rates, tending to lower the former and to raise the latter. Cholera swept off a greater number of people than in any previous year since the introduction of the registration of vital statistics. The severity of the epidemic is attributed mainly to climatic conditions. Absence of rain, and excess of rain, were both, it is stated, favourable to cholera prevalence. The death-rate from small-pox, though higher than usual, was not excessive, except in districts in which inoculation is practised and preferred by the people to vaccination. In such districts, when vaccination has been placed within the reach of all, there would appear to be no valid reason against the suppression of inoculation. The mortality from diarrhœa and dysentery was higher than usual ; but there are reasons for believing

that the recorded death-rates attributed to these diseases do not represent, even approximately, the actual rates. According to the Sanitary Commissioner, deaths from plague are generally returned under the head of fever; if such be the case, the plague mortality returns must be accepted with reserve. The most important of the sanitary schemes under consideration, that for providing a combined water-supply for the riparian municipalities, would be of the utmost benefit to the populations concerned. The scheme will be costly, and the chief difficulty in carrying it out, the provision of the necessary funds.

24th April, 1902.

No. 3.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the North-Western Provinces and Oudh for the year 1900.

The Report covers only 14 pages, or little more than half the maximum number prescribed by the Government of India. The year was a very healthy one. The birth-rate of 40·34, per thousand of population, although much below that of the previous year, was still considerably higher than the mean rate for the previous five years. Whilst the birth-rate decreased from 48·09 in the preceding year to 40·34, the death-rate at the same time decreased from 33·19 to 31·13, and was below the quinquennial mean. A decrease of the death-rate is, under ordinary conditions, a normal accompaniment of a decrease of the birth-rate. But for the unusually high birth-rate of the preceding year, the effect of which would continue to influence the mortality returns of the year immediately following, the death-rate of 1900 would doubtless have shown a still further decline. The births during the year under review exceeded the deaths by 432,030, a number which represents the natural increase of the population.

2. In paragraph 15 of the Report the infantile death-rate is stated to have been 219·2; but on referring to Annual Form No. IV. in the Appendix, the ratio of deaths of children under one year of age, per 1,000 living, is seen to be 286·96 for males and 267·00 for females. If the infantile death-rate is calculated on the number of births during the year under report instead of on the number of children under one year of age according to last census, it will be found to be 240·2 per *mille*. For the previous year the infantile death-rate similarly calculated was 230·5. The death-rates among children under one year of age during each of the two years 1899 and 1900 are thus seen to approximate much more closely than the figures in paragraph 15 of the Report would indicate. How these latter are arrived at is not clear. If the number of children under one year of age, according to last census, is used in calculating infantile death ratios, a glance at the figures in paragraph 15 will show that the smaller number of deaths in 1898 is made to yield a higher ratio of deaths than the larger number in the year under report.

3. Returns of deaths, the causes of which have been verified by medical officers, medical subordinates, and medical practitioners, have been, as usual, obtained during the year under report. The total number of these cases was 11,321. Of these, 2,022 were attributed to malarial fevers, and 2,122 to dysentery and diarrhœa. The deaths from the latter two diseases were, thus, more numerous than those from malarial fevers. In the provincial returns the recorded death-rate from fevers was 23·58; whilst that from dysentery and diarrhœa was only ·65, per thousand of population. Although it would be unsafe to draw general conclusions from numbers so small as those in which the causes of death have been verified by qualified medical practitioners, yet, so far as they go, the results, like those obtained in previous years, tend to show that, whilst the provincial returns overstate the mortality from fevers, they greatly understate that due to bowel complaints. Amongst the 11,321 deaths, the causes of which were verified by medical practitioners, 19 were ascribed to enteric fever in the year under report, as compared with seven out of 9,684 deaths in the previous year. It does not appear that any of those deaths from enteric fever occurred amongst the 4,794 children under 16 years of age. The systematic check of registers and the infliction of fines for neglect to record births and deaths have, by degrees, been effectual in these provinces in rendering the returns of vital statistics approximately accurate as regards mere numbers; but the same cannot be said of the causes assigned for the deaths recorded in the returns; and with the agencies available for ascertaining these causes, it is not probable that this defect in registration will soon be overcome.

4. *History of Chief Diseases.*—The deaths due to *cholera*, which had numbered only 2,508 in 1898 and 8,142 in 1899, increased to 84,960 in the year under review. The causes to which these great variations in the prevalence of cholera from year to year are due, have yet to be discovered. A suggestive remark is made by the Sanitary Commissioner in paragraph 30 of his Report, when noting the absence of cholera at the great fairs held during the year. "In past years these gatherings were constantly the origin of widespread sickness and death. It is difficult to attribute the immunity from such outbreaks in recent years to anything but improved and systematic sanitary measures."

5. Small-pox deaths decreased in number from 2,096 in the preceding year to 1,410 in the year under report. The latter number yields a mortality rate of only ·03, per thousand of population, the lowest hitherto recorded for the Province. Vaccination made good progress, in spite of the need for caution in carrying out vaccine operations in those parts of the Province where plague prevailed, and of the deputation of some of the most experienced vaccinators on plague duty. The percentage of success was high both in cases of primary vaccination and of re-vaccination. "Calf lymph is only used at present to a small extent, arm-to-arm vaccination being generally practised throughout the Province." Arrangements are, however, being made for the provision of bovine lymph in sufficient quantity to make recourse to the use of humanised lymph no longer necessary.

6. The death-rate from *fever* decreased from 26·55 in the previous year to 23·58 in the year under report. *Diarrhœa* and *dysentery* are credited with only 30,652 deaths; but, as already remarked, the actual mortality from these two diseases is probably far greater than the returns would indicate.

7. The Sixth Annual Report of the Provincial Sanitary Engineer gives a detailed account of the sanitary works executed during the year. These consisted largely of improvements and repairs in connection with waterworks already completed. The Benares drainage scheme made substantial progress, and the question of the best method of disposing of the sewage of Cawnpore was gone into. With regard to sanitation, Colonel Thomson says:—"Many sanitary improvements have been effected, not only in the larger cities and towns, where special sanitary and health officers were employed, but also in rural areas, which have been visited from time to time by medical and other officers in connection with plague preventive measures."

8. *Summary.*—Judged by its birth and death rates, the year was prosperous and healthy. The birth-rate did not reach the exceptionally high level of the previous year, but was still over 40 per thousand of population. The death-rate fell along with, and partly doubtless as a result of the fall in, the birth-rate. In all probability it would have been still lower but for the unusually large proportion of infants in the population consequent upon the high birth-rates of the previous year and of the year under report. It is not understood how the "death-rate of infants" given in paragraph 15 of the Report is arrived at. The Government of India are not inclined to accept anything below a death-rate of 300 as being an approximately true figure of the infantile death-rate in India. The deaths from cholera, which were only 2,508 in 1898 and 8,142 in 1899, numbered 84,960 in the year under review. Some attempt might have been made to explain why, after remaining for two years in comparative abeyance, cholera should have broken out with such violence in the year under report. The small-pox mortality of the year is the lowest on record, a result which may fairly be credited to the progress and efficiency of vaccination. The results obtained from the records of deaths, the causes of which have been verified by qualified medical practitioners, support the belief that the number of deaths attributed to diarrhœa and dysentery in the provincial returns is much understated, and the number attributed to fevers overstated. No new sanitary works of magnitude were commenced during the year; but much was done to improve and perfect existing waterworks and to advance towards completion the great drainage scheme at Benares.

24th April, 1902.

No. 4.

MEMORANDUM by the ARMY SANITARY COMMISSION on the REPORT of the SANITARY COMMISSIONER of the PUNJAB for 1900.

In accordance with the orders of the Government of India the length of the Sanitary Report for the year has been much reduced. It does not much exceed half the maximum length of 20 pages, to which it has in future to be limited. The year was one in which the population of the Punjab suffered severely from the combined effects of famine and sickness. The only other Indian provinces in which higher death-rates were recorded were those of Bombay and the Central Provinces; and in both scarcity and famine were more widespread and severe than in the Punjab. Instead of wages rising as the price of food rose, labourers "were found willing to work for lower wages owing to increased competition during the famine."

2. The *birth-rate*, although lower than in the previous year, was still higher than in any other Indian province. This result the Sanitary Commissioner attributes "entirely to the effective method of registration." Without denying to efficient registration its share in bringing about the record of a high birth-rate, it is certain that the growth of the population since the previous census was taken must have exercised a decided effect in raising both the birth and death rates recorded for the year under review, the last of the ten inter-censal years. The census figures for 1891 are used in calculating birth and death rates; but the new census figures for 1901 show that the population of the British part of the Province has increased during the past 10 years by upwards of a million and a half, or at the rate of 7·57 per cent. The district of Jhang furnishes an example of the effect on the birth-rate which increase of the population since the previous census may produce. The birth-rate recorded for Jhang in the returns for the year under review is 77·7 per thousand, calculated on its population figures of 1891. But the census of 1901 shows that, during the preceding 10 years, the population has increased by no less than 734,625. If calculated on the census figures of 1901 the birth-rate works out to be, not 77·7, as recorded, but only 28·98.

3. The *death-rate* rose from 29·57 in the previous year to 47·7 per thousand of population. This increase is ascribed to famine, cholera, and fever. If in calculating it the census figures of 1901 are used, the death-rate, like the birth-rate, will be found to be lower than that obtained by calculating it on the population figures of the previous census. Using the census figures of 1901 the death-rate works out to be 43·9, and using the census figures of 1891 to be 47·7. The famine-stricken districts show, as might be expected, the highest death-rates. In the Hissar district, in which to severe famine was added an epidemic of cholera, the death-rate rose to 96·4 per *mille* of population. An examination of the returns of deaths shows that, whilst the number of male children born exceeds the number of female children born, yet in some districts the number of the latter who die under one year of age exceeds the number of the former. In the three districts of Jullundhur, Ludhiana and Amritsar, this excess of mortality amongst female infants is a constant feature of the returns from year to year. The fact, as observed in the Government review of the report, "cannot be without its significance."

4. *Chief Diseases.*—Of deaths from *plague* 495 were reported, as compared with 227 in the previous year. *Cholera* prevailed in severe epidemic form, and accounted for 28,260 deaths, yielding a death-rate of 1·37 per *mille* of population, as compared with an average of only 0·08 for the previous five years. "The severity of the epidemic," writes the Sanitary Commissioner, "was due in great measure to the presence of famine in the Province." Yet, the history of cholera in other years and provinces shows that the prevalence and severity of this disease may bear no proportion to the degree and severity of famine. In the year 1897 widespread and severe famine prevailed in the North-Western Provinces, yet, although cholera was present, it was less destructive of life than in years when there was no famine. In 1897, in those provinces the cholera death-rate was only 0·94 as compared with 1·47 in the previous year, and with an average for the five previous years of 2·16. Similarly, although Bihar was the most severely famine-stricken part of Bengal in 1897, it recorded a lower death-rate than any other division of the Province. The attempts made to explain the origin of the outbreaks of the disease in the Punjab have not been attended with much success. In the district of Hissar, which suffered much more severely than any other in the Province, "the disease was reported to have broken out on the 13th December, 1899, in consequence of the contamination of a tank, the water of which was used by famine relief labourers, but it is not known how the tank was contaminated." So, with regard to the instances in which the origin of outbreaks was ascribed to importation, "the evidence," writes the Sanitary Commissioner, "is of so conflicting a nature that no reliance can be placed on it."

5. *Small-pox* caused 10,425 deaths, or a ratio of 0·51 per *mille* of population. The numbers vaccinated during the year show a great falling-off as compared with the numbers for the preceding year. The decrease, which amounted to 160,578, is attributed to the decrease in the number of births, and to the fact that in the preceding year the numbers vaccinated were much in excess of the annual average. Of the total of 592,824 successful primary vaccinations, no fewer than 462,392 were performed on children under one year of age; and as the number of children born in the year under report fall short by 150,031 of the number born during the previous year, it is evident that the diminished birth-rate must have had a marked effect in diminishing the number available for vaccination. The large proportion of infants vaccinated is a favourable feature of vaccination work in the Punjab. The results obtained from the use of vaccine lymph preserved with glycerine have been disappointing. In the two districts of Umballa and Rawal Pindi, for which returns are given in Appendix C., the percentage of successful, excluding "unknown," cases was only 92·30. It might be found expedient to adopt in the Punjab the method of lymph preservation with glycerine which Colonel Campbell found to yield so successful results in Assam.

6. *Fever* is credited, as usual, with having caused by far the greater proportion of the deaths from all causes. According to the returns, 70 per cent. of all the deaths were due to it; but no doubt a large number of deaths due to other causes are registered under this head. The fever death-rate, which averaged during the previous five years 19·54 per *mille* of population, rose during the year under report to 33·37. In the severely famine-stricken district of Hissar it reached the high ratio of 70 per thousand. The Sanitary Commissioner says the rise in the fever mortality took place in September in consequence of the heavy rainfall in that month. The deaths ascribed to it in the following two months exceeded a quarter of a million.

7. The ratio of mortality from *diarrhœa* and *dysentery* rose from 0·53, the average for the previous five years, to 1·26 per thousand of population in the year under report; but it is probable that the actual death-rate from these scourges of communities suffering from scarcity of wholesome food was far higher than that recorded. The very useful return published year by year in the Sanitary Report of the North-Western Provinces, embodying the results of the verification of deaths by qualified medical men, shows that, there at least, the proportion of deaths due to diarrhœa and dysentery probably far exceeds the proportion shown in the general provincial returns; and that, on the other hand, the proportion ascribed to fever is greatly overstated.

8. The amount of money expended on them affords, perhaps, the most reliable measure of the progress being made in the improvement of the water-supplies and drainage of the towns of the Province. The total municipal income for the year exceeded 46 lakhs of rupees; and from this amount a sum of less than three lakhs was devoted to the improvement of the water-supplies, and just over a lakh to the improvement of drainage. From this it may be concluded that no sanitary work of magnitude was carried out during the year. The appointment, just made, of a Sanitary Engineer for the Province may be taken as an indication that sanitary works are, in future, to receive increased attention, and to be designed and executed on scientific principles.

9. *Summary.*—The year was unhealthy. Owing to the prevalence of famine and epidemic diseases, the mortality of the Province, as a whole, was abnormally high, and in some of those parts most severely afflicted by famine, excessive. Whilst the birth-rate decreased from 48·4 in the preceding year to 41·1 in the year under report, the death-rate increased from 29·5 to 47·7. For this increase of the death-rate fever was chiefly responsible. Fever by itself caused no less than 70 per cent. of the deaths from all causes, according to the returns. Cholera, which in the Punjab prevails in severe epidemic form only at long intervals, accounted for upwards of 28,000 deaths. Diarrhœa and dysentery had ascribed to them a death-rate of 1·26 per thousand of population, but the actual death-rate from these two diseases was probably much higher. Small-pox was more than usually prevalent and fatal. The numbers vaccinated during the official year 1900–01 greatly fell off, the decrease being ascribed, in part, to the decrease in the number of children born during the year. Plague deaths to the number of 495 were registered in three districts; this was more than twice the number recorded in the previous year. The appointment of a Sanitary Engineer for the Province may be taken to indicate an increasing appreciation of the importance of sanitary works, and a determination to have these designed and executed in accordance with scientific requirements.

24th April, 1902.

No. 5.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Burma for 1900.

The Report, which is clear and concise, covers only 17 pages. The sanitary history of the year did not much differ from that of its predecessor; both were healthy years. The Province suffered from no very serious outbreak of epidemic disease, and the number of deaths recorded was nearly the same in each of the two years.

2. Continued attention is being paid to the important work of *registration* of vital statistics and improvement is shown to be taking place; but the Sanitary Commissioner gives good reasons for believing that, in some cases at least, the scrutiny to which the registers of births and deaths are subjected by inspecting officers is wanting in thoroughness; "for it is scarcely possible that registration, especially in rural tracts, can be so very accurate that only one omission occurs in 4,761 entries, and no omissions in 4,085." In Upper Burma, except in some selected towns with a combined population of 311,605, registration of births has not yet been commenced; but the deaths are registered for a population of nearly two and a half millions. The ratio of births recorded in the selected towns approximates to the ratio for Lower Burma; but in the case of deaths it is only 21·80 as compared with 27·51. As regards deaths, at all events, it is clear from these figures that a large proportion of them must remain unregistered.

3. The number of *births* recorded during the year in Lower Burma shows a considerable increase over the number recorded in the previous year, and a large increase over the decennial mean. The birth-rate, which was 37·04 in the previous year, rose to 38·37 in the year under review. The number of births exceeded the number of deaths by 11 per thousand of population. The increased birth-rate may, in part, be due to improved registration; but there is little doubt that it is also, in part, due to growth of population since the census of 1891 was taken. This growth may not be altogether the result of what is termed "natural increase," or excess of births over deaths; but may, in part, be due to immigration. Unlike some congested parts of India, Burma has still room for a larger population than it yet possesses. Contrary to what might be looked for, the registration of births seems to be more defective in towns than in rural tracts. Whilst the birth-rate recorded in the former was only 27·55, per thousond of their population, in the country it was 39·06. In the Province as a whole, for every 100 births of female children there were 107 births of males. This proportion does not probably diverge much from normal, and may be accepted as another indication that, under persistent attention given to it, registration is making good progress.

4. The *deaths* registered in Lower Burma during the year numbered 172,714, or 943 over the number for the previous year. Calculated on the population numbers of the previous census this gives a ratio per thousand of 27·51 as compared with 22·44, the mean of the previous ten years. Improved registration and growth of population since last census, the factors assumed to have been chiefly concerned in raising the birth-rate of the year under review, were also probably those chiefly concerned in raising its death-rate. The mortality in towns was much higher than in the country; in the former the death-rate recorded was 32·70 as compared with 26·71 in the latter. The Sanitary Commissioner remarks that the towns in which the death rates were lowest also return low birth-rates, "due, evidently, to defective registration." The cause assigned may be the real one for the lowness of both the birth and death-rates recorded; but a low birth-rate normally accompanies a low death-rate, as a high birth-rate normally accompanies a high death-rate. By far the greater proportion of deaths was registered under the two headings, "other causes" and "fever." Together, these two contributed 23·92 of a total rate from all causes of 27·51.

5. Of the *chief diseases* none was unusually fatal during the year. *Cholera*, which is shown by the returns to be, in the words of the Sanitary Commissioner, "more or less always with us," accounted for a death-rate of ·77 per thousand of population, as compared with 1·11 in the previous year, and with a quinquennial mean of 1·09. The detailed reports submitted by Civil Surgeons are said to elucidate nothing new in the origin or spread of the disease; but "it may be remarked, however, that an impure or infected water-supply was usually associated with these outbreaks."

6. Like cholera, *small-pox* was less fatal than in the preceding year. The death-rate from this cause fell from 1·32 per thousand, in 1899 to ·68 in the year under review. The number of primary vaccinations for the official year 1900–01 fell from 456,762 in the previous year to 395,652; whilst the percentage of success fell, at the same time, from 94·71 to 91·69. Great as the decrease is, it is not to be deplored, if the Sanitary Commissioner is correct in assigning it to stricter supervision and to the check which the submission of falsified returns by the vaccinators has received. Vaccination can never be successfully carried on without a continual supply of good vaccine lymph; and unfortunately this does not appear to have been always available. The Sanitary Commissioner writes:—"The quality of lymph throughout the year was not satisfactory." Lanoline, glycerine and lanoglycerine were all used in the manufacture of the lymph. In last year's *memorandum* it was suggested that the process of manufacture adopted with such marked success by Colonel Campbell in Assam might be tried in Burma. Outside municipal limits the inoculator is free to practise his craft with impunity, the Courts having ruled that inoculation is not a punishable offence under the Penal Code. The consequence is, that the inoculator is said to be found working side by side with the vaccinator, often forcing the latter from the field and keeping up a perpetual source of small-pox infection. The Sanitary Commissioner, in consideration of the gravity of this evil, thinks the Government might interfere in the interests of the public safety to put a stop to inoculation. Now that vaccination has been made available for all, and as it is at least as effectual a protection against small-pox as inoculation, there would not seem to be any hardship or injustice in putting a stop to the practice of the latter.

7. The mortality from *fever* and *bowel complaints* was nearly the same as in the previous year, and also nearly the same as the mean for the previous five-year period.

8. Four cases of *plague* were reported during the year, but the measures adopted to prevent the communication of the disease to the indigenous population proved successful. Of the four cases, all of them imported, only two were definitely shown to be genuine cases of plague. Of the remaining two cases, although they were perhaps doubtful, the Sanitary Commissioner is not prepared to say that they were not plague. The successful endeavour to prevent the spread of plague was in no small degree due to the vigilance and energy of the Port Health Officer of Rangoon, a brief account of whose work is given as an Appendix to the Sanitary Report.

9. *Sanitary Works.*—"Prome was the only town on which anything appreciable was expended on water-supply or drainage." Several schemes for improving the water-supply of other municipal towns were under consideration. Of these the most important is that for the improvement of the water-supply of Rangoon. The present supply, which is obtained from two lakes, is not filtered and has been repeatedly pronounced by the Chemical Examiner to be unfit for drinking purposes. Within the catchment area of one of the two lakes "are several vegetable gardens where night-soil is used as manure, as well as the homesteads of the Chinese and Burmese gardeners who cultivate them." A new scheme is to be taken in hand without delay at a cost of over eleven lakhs of rupees. Chief features of this scheme are the discontinuance of the lakes as sources of supply, and the formation of another great storage reservoir, the water from which will pass into settling tanks and through filter beds before its distribution to Rangoon.

10. *Summary.*—The year, like its predecessor, was healthy. Registration of vital statistics continued to receive much attention. The births recorded in Lower Burma show an increase over the number for the previous year, and exceeded the number of deaths by 11 per thousand of the population. The death-rate was nearly the same as in the preceding year. None of the chief diseases was unusually prevalent or fatal. A few imported cases of plague were detected at Rangoon, but the disease did not spread to the indigenous population. Excepting the town of Prome, none of the other municipalities expended any considerable sum on the improvement of waterworks or drainage. A scheme is to be taken in hand without delay for providing Rangoon with a water-supply from another source, the supply at present obtained from the Royal Lakes having repeatedly been pronounced by the Chemical Examiner to be unfit for drinking purposes.

24th April 1902.

No. 6.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Central Provinces for 1900.

Before the preceding very healthy year had closed, there were indications that its successor would be one of unusual sickness and mortality. The failure of the rains of 1899 was followed by severe famine in the year under report, and in the company of famine came destructive epidemics of disease. The deaths were more than double the number recorded in the previous year, and more than the number recorded in any one of the previous 20 years, excepting only 1897.

2. The fluctuations in the *birth-rate* which have occurred during recent years in the Central Provinces furnish illustrations of the effects which conditions of distress, alternating with those of prosperity, exercise on fecundity. The period 1897–1900 includes two years of severe famine, and two years in one of which the birth-rate was the lowest and in the other the highest on record. It can readily be understood that, although, as regards deaths, the period of increased mortality would coincide with the period of famine, this might not be the case as regards births; some time would elapse after the commencement of famine before its effects would show themselves in a reduction of the number of births. During the year under report the birth-rate fell to 31·90 from 47·3 in the preceding year.

3. At the same time that the birth-rate fell so greatly, the *death-rate* more than doubled. This latter, which had been 28·09 in the previous year, increased to 56·75 in the year under review, but still fell far short of that recorded for the previous famine year of 1897, when it was 69·34. The Chief Commissioner in his review of the Report notices one of the reasons which might, in part, account for the lower mortality of the famine year 1900 as compared with that of the famine year 1897, notwithstanding that the "actual physical famine-producing conditions in 1897 were much less severe in extent and degree than in 1900." As he observes: "the power of resistance on the part of the population in 1900 would naturally be greater after an elimination of the weakly such as the famine of 1897 must have brought about." On the other hand, as a consequence of the abnormally high birth-rate of the preceding year, the population of the year under report contained an unusually large proportion of infants; and the mortality amongst infants being far higher than amongst those who have passed the period of infancy, this increase in their number conduced towards increase of the death rate. The number of infant deaths during the year under report "was extremely high, the total being 145,916, compared with 101,969 in the famine year 1897." In the Province, as a whole, the deaths at all ages and from all causes exceeded the births by 24·85 per *mille.*

4. The work of verifying the registration of vital statistics is said to have suffered no neglect in consequence of the extra strain thrown by famine relief operations on the officers of all departments of the public service. On the contrary, as regards deaths at least, it is believed that more than usual care was bestowed upon their registration. The Administrative Medical Officer, however, thinks it

more than probable that the figures recorded do not include all the births and deaths that occurred. The method adopted by the Native Superintendents of Vaccination for testing registration, described in paragraph 27 of the Report, would not fail, if rigorously carried out, to detect errors in the record of births and deaths. In the paragraph immediately preceding that just mentioned, there is a statement which seems to need explanation. "Of 48,603 births and 70,262 deaths reported by kotwars, it was found that 48,721 births and 70,294 deaths were recorded by the police." That is to say, the number of births and deaths entered in the register at the police station was greater than the number reported by the village watchmen. If the watchman's hand-book is written up in his village, the births and deaths in it are simply copied from it into the register at the police station. But, in some cases, the entries in the watchman's hand-book are not made in his village, because the watchman cannot himself write, and may be unable to find anyone in his village to write for him. In such a case, the watchman reports from memory at the police station the births and deaths which have taken place in his village since his last visit, and the clerk enters these both in the police register and generally in the watchman's hand-book as well. The agreement between the entries in a watchman's hand-book and the police register would, thus, be no guarantee of the accuracy of the registration of births and deaths. The village watchman might neglect to enter many of these events in his hand-book, or forget to report them to the clerk at the police station, and yet the hand-book and police register might agree. It seems desirable to explain this, as we read in paragraph 33 of the Report :—"The Civil Surgeon of Jubbulpore states that he compared the kotwar's books in 508 villages with the police registers, and that out of 6,857 births and 6,746 deaths entered in the former, he found 6,819 births and 6,775 deaths recorded in the latter." From this comparison the Civil Surgeon concludes that the "registration of births and deaths in the rural circles is wonderfully correct, and that in the cities and towns, with the exception of Murwara, it is also very correct." But such a method of testing the accuracy of the registration of births and deaths merely shows that the entries in the kotwar's books have been more or less correctly transcribed into the police registers; it is no proof that the kotwars have correctly reported the births and deaths in their villages. Only a house-to-house enquiry and a comparison of the result of such inquiry with the entries in the watchmen's books, or with the entries in the police register, can establish the accuracy or inaccuracy of the registration of births and deaths.

5. *Chief Diseases.*—The measures adopted with the object of preventing the spread of *plague* in the Central Provinces appear to have been attended with marked success. The number of deaths from plague only increased from 583 in the previous year to 590 in the year under report. "It is remarkable," writes the Sanitary Commissioner, "how these Provinces, lying as they do in the very pathway of, and surrounded by, infection, have so far, and with the slight exceptions mentioned, escaped the ravages of the disease."

6. *Cholera* was credited with 63,114 deaths; "but there is little doubt that many deaths occurred from cholera which were not reported as such, and what strengthens this opinion is the fact that the non-epidemic mortality rose directly cholera became general in March and April, and declined in September and October when cholera was dying out." The use of the permanganate of potash in the disinfection of the water supplies in localities in which cholera outbreaks occurred is reported to have been "generally attended with good results." The question of the efficacy of the permanganate of potash in cutting short cholera outbreaks by destroying cholera infection in the water supplies is one which, as we have noted in other memoranda, should be submitted to scientific investigation. At present, although many medical officers are convinced that the permanganate rarely fails to put a speedy end to a cholera outbreak, there are others who withhold their assent to this conclusion until definite proof can be produced in support of it.

7. *Small-pox* accounted for upwards of seven thousand deaths, or a ratio of 0·7 per 1,000 of population. From a remark made by the Administrative Medical Officer, he appears to imply that the invasion of the Central Provinces by small-pox was due to extension of the disease from the Bombay Presidency. "It made its entry from the Bombay side and invaded every district but one." But, apart from the circumstance that small-pox was less prevalent in the Bombay Presidency during the year under report than in the Central Provinces, the monthly returns show that in these latter no fewer than 10 districts were affected with the disease during the first month of the year, and between them recorded in that month 354 deaths. Some of these 10 districts, such as Sambalpur and Hoshungabad, are far removed from the Bombay side. The work of vaccination is stated to have been carried on during the year in a satisfactory manner; and, taking into account the difficulties it had to contend with in consequence of the prevalence of famine and pestilence, this was no doubt the case. But the number of primary vaccine operations was less by 66,141 than in the preceding year, although there was, on the other hand, an increase of 19,202 re-vaccinations. The percentage of successful primary and re-vaccination operations shows some decrease. The large decrease in the number of primary vaccinations is attributed to the diminished number of children born and the excessive infant mortality during the year. Although in the greater number of vaccine operations animal lymph was used, the returns show that arm-to-arm vaccination was practised in over a fifth of all the cases. The calves inoculated for the supply of vaccine lymph reached the enormous number of 10,228. One calf, on the average, would thus appear to have supplied lymph for the vaccination of only about 29 persons. As noted in last year's *memorandum*, in the Province of Assam one calf yielded sufficient lymph when mixed with glycerine to charge 1,047·46 capillary tubes. In the Central Provinces, a percentage of not more than 86·97 successful cases was obtained when glycerinated lymph was employed. The percentage of success resulting from the use of all kinds of lymph during the year was 96·97.

8. During a year in which scarcity of food was accompanied by scarcity of drinking water it was only to be expected that the mortality from *fever*, and especially from *bowel complaints*, would be great. The fever deaths, of themselves, exceeded in number those from all other causes of death together. No doubt, however, as the Administrative Medical Officer observes, many deaths due to other causes are recorded under the head of "fever," especially deaths due to acute diarrhœa or dysentery.

9. As the Chief Commissioner remarks, the Report might have been curtailed with advantage by the omission of details regarding sanitary works in rural and urban areas. Except in the town of Jubbulpore, no drainage work of magnitude was in progress during the year. In some of the other towns attention was directed to the improvement of the water supplies; but in a year of such stress, costly works of sanitary improvement would necessarily have to stand over until the return of more prosperous times.

10. *Summary.*—The year was a calamitous one. Famine and disease combined to raise the death-rate above that recorded in any one of the last twenty years, excepting 1897. The birth-rate fell from 47·3 in the preceding year to 31·90. Plague was still present, but owing doubtless to the measures taken to deal with it, showed little tendency to spread, and was credited with only about the same number of deaths as in the previous year. Cholera, small-pox, fever and bowel complaints were excessively fatal. The use of the permanganate of potash as a disinfectant of water supplies is believed by many medical officers to have been efficacious in cutting short outbreaks of cholera. The number of primary vaccinations greatly decreased; whilst that of re-vaccinations considerably increased. Glycerinated calf lymph gave a percentage of only 86·97 successful cases; and no fewer than 10,228 calves were inoculated for the supply of the Province with calf lymph. Yet, over a fifth of the total number of operations were performed with humanised lymph. In a year of scarcity of food and drinking water it was only to be expected that fever and bowel complaints would be unusually fatal. Excepting the drainage works at Jubbulpore, no others of magnitude were undertaken during the year. In some of the other towns attention was given to the improvement of the water supplies. Sanitary progress was retarded by the need for the employment of all available funds in combating famine and epidemics of sickness. The Report might have been considerably curtailed by the omission from it of details of sanitary improvements in rural and urban areas.

No. 7.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Assam for 1900.

Last year the Report covered 27 pages; this year it has shrunk to nine. No doubt, as the Chief Commissioner remarks, the former reports were too long; but the present one, he thinks, errs in the opposite direction. No mention is made of the rainfall or other chief meteorological features of the year, or of the prevailing prices of food; yet a report claiming to give even the briefest sketch of the sanitary history of a province, cannot well dispense with some allusion to the influence which climate and food supplies appear to exercise on the health of the people. It is stated that the health of the Province for the year was, on the whole, fairly good; and this statement is borne out by the comparatively low death-rate recorded.

2. Throughout the Report, the new population numbers of the recent census of 1901 are used in calculating ratios. The population, according to the previous census of 1891, numbered 5,050,590, and according to that of 1901 is now 5,275,249. Much attention continues to be devoted to the improvement of the registration of vital statistics. The statements given of the numbers of births and deaths checked in each district appear to show that the police afford very valuable aid in testing the accuracy of the registers. The same can hardly be said of the Inspectors of Vaccination; in four of the eight districts of the Province, these officers, as the result of their examination of the registers of births and deaths, failed to detect any inaccuracies. Judging from the number of births and deaths ascertained by the police to have been omitted from the registers in these same districts, it is more than probable that the checking of registers by the Inspectors of Vaccination was perfunctorily performed.

3. The provincial *birth-rate* of 34·96 shows a slight decrease when compared with that recorded for the previous year, when it was 35·45; but was higher than the rate recorded for any one of the three years preceding 1899, and higher than the average ratio of the 10 years ending 1896. A glance at Annual Form No. 1. in the Appendix reveals startling differences between the birth ratios of the several districts. Whilst Goalpara district records a rate of 41·06, everyone of the other five districts of the Brahmaputra Valley records a birth-rate of less than 30, and two of them rates of only 22·96 and 22·23 each. As registration has hitherto been stated to be more efficiently carried out in the Goalpara district than in any other districts of the Brahmaputra Valley, it may be inferred that the very low rates recorded in the latter are due, in part at least, to defective registration.

4. The *death-rate* for the Province was 30·64, per thousand of population. This is lower than the rate recorded for any of the other provinces of India except Burma and Madras. As in the case of the birth-rates, so in the case of the death-rates there are striking differences between those recorded for the several districts. Whilst Nowgong records a death-rate of 53·03 and Darrang of 44·09, the districts of Sibsagar and Lakhimpur record rates of only 20·78 and 25·62 respectively. As regards these two last districts, each records an abnormally ow birth-rate, the ordinary concomitant of a low death-rate. Disturbing causes may, however, upset this relationship between the birth and death rates. For example, the Nowgong district returns a birth-rate of only 27·91, per thousand of its population, whilst it returns a death-rate of 53·03. Besides being the most unhealthy of the districts of Assam, Nowgong was, during the year under report, visited by a destructive epidemic of cholera, which of itself swept off no less than 24·9 per thousand of its population.

5. *General History of the Chief Diseases.—Cholera* was much more fatal than in either of the two preceding years; the deaths attributed to it numbered 23,761 as compared with 8,380 in the previous year, and with 11,288 in 1898. In his report for the preceding year the Sanitary Commissioner

wrote :—"The incidence of the disease on tea gardens is always more severe than elsewhere ; in fact epidemics frequently start from them, and as most batches of coolies coming up by steamer or rail are infected, it is no wonder the managers cannot keep their estates clear." In his Report for the year under review we find :—"It is worthy of note that instead of the rate for cholera in tea gardens being higher than in other parts of the Province, as is generally the case, in the year under review it was much less." Conclusions drawn from the history of cholera in previous years are liable to be upset by its behaviour in succeeding years. As bearing on the importation of the disease in Assam by infected coolies coming from other provinces, a remark made by the former Sanitary Commissioner in his account of the severe epidemic of 1897 is worth quoting :—"The Surma and Brahmaputra Valleys are within the endemic area, and, in accordance with ordinary experience, deaths from this disease were registered in all the districts of these two valleys in each month of the year." The table given in the fifth paragraph of the Government review of the Report, shows the number of deaths from cholera amongst immigrant coolies on the steamers and at the depôts for the past five years. These deaths increased from 92 in the previous year to 528 in the year under report, notwithstanding the greatly improved sanitary arrangements effected in recent years on the steamers conveying tea-garden coolies to Assam. The state of health of these immigrant coolies at the time of their embarkation cannot fail to influence their death-rate. Quoting from the Chief Commissioner's Review of the Report :—"It is presumed that the heavy mortality is due to the large number of famine-stricken coolies who were predisposed to disease." An examination of the table referred to shows that the rise and fall of the cholera death-rate among immigrant coolies accompanies a corresponding rise and fall in the cholera death-rate for the Province. The significance of this relation might point to opposite conclusions. The greater prevalence of cholera amongst immigrants might be taken, by those who support the doctrine of importation of cholera infection, to be the cause of the greater prevalence of the disease amongst the provincial population. On the other hand, the greater prevalence of cholera among the coolies might be assumed to be the result of their entry into a country already infected ; cholera being shown to be endemic in Assam. A feature of the year's history of cholera was the disappearance of the disease, "almost as if by magic," after the sudden outburst which took place in March and continued until the end of June. Had any special measures, such as the disinfection of the water-supplies by permanganate of potash, immediatety preceded this sudden disappearance of cholera, such measures would not unnaturally have been given the credit of having cut short the outbreak.

6. The number of deaths due to *small-pox* decreased from 1,453 in the preceding year to 975 in the year under review. Of this disease the Sanitary Commissioner writes :—"Now, I think I may fairly say it plays quite an insignificant part in producing mortality in any portion of the Province, as is clearly shown by the statement printed in the margin." The comparative immunity of the Province from small-pox mortality, he thinks, "speaks volumes for efficiency of the work of vaccination." The Report on vaccination for 1900-01 shows that there was a slight falling-off in the number of primary vaccinations and of re-vaccinations, accompanied by a very considerable falling-off in the percentage of successful cases. In primary vaccination the percentage of success decreased from 98·50 in the previous year to 95·99 in the year under report ; whilst in re-vaccination it decreased from 88·90 to 79·99. The first two supplies of lymph sent out at the beginning of the working season are said to have been, for some unknown reason, of inferior potency, and their use to have been followed by a large number of failures. It is added that, under the insistance on more rigid rules and supervision, the normal efficacy of the lymph was promptly restored.

7. The mortality from *fevers*, which had decreased in the previous year to 18·04 per thousand of population, from 20·95 in 1898, still further decreased in the year under review to 14·70. Accompanying this decrease the returns show a steadily diminishing prevalence of the fatal form of fever known as *kalá-ázár*. The number of deaths recorded under the head of *kalá-ázár* has fallen from 18,597 in 1897 to 9,012 in the year under report. The Sanitary Commissioner in his previous report expressed the opinion that the epidemic of this disease might be said to be surely, if slowly, ceasing.

8. The death-rate from *diarrhœa* and *dysentery* was almost the same as in the previous year ; in 1899 it was 2·75 and in the year under report 2·84. The Sanitary Commissioner is unable to understand why these diseases should be so much more fatal in some districts than in others, and is inviting the special attention of civil surgeons to the solution of this question. Whilst the Goalpara district returns a death-rate from diarrhœa and dysentery of only 0·33 per thousand of population, Sibsagar returns a rate of 5·65, and Lakhimpur of 7·70. Possibly, the difference may be, in part, due to difference in diagnosis. It is almost, or altogether, incredible that in the Goalpara district, out of a total death-rate from all causes of 84·45, only 0·33 should be due to diarrhœa and dysentery.

9. *Sanitary Works.*—"No very large sanitary work was undertaken last year, and there is at present no provincial scheme of any importance under consideration." The list of sanitary improvements in rural areas shows that, with the funds available, a good deal is being done towards the improvement of the water-supplies by the construction of wells and the excavation of new tanks, or the repairing, cleansing, and protecting of existing ones. The money could not be spent to better purpose than in improving the water-supply. The total amount, Rs. 10,685, expended by the nine municipalities of the Province on drainage seems small, as does the total of Rs. 21,700 on water-supplies. But much cannot be expected of municipalities with populations ranging from only a little over 4,000 to less than 15,000 each.

10. *Summary.*—The Report has, in accordance with the orders of the Government of India, been much abbreviated. The year was, on the whole, a fairly healthy one, apart from the severe epidemic of cholera which carried off upwards of twenty-three thousand of the population. There was decreased mortality from small-pox and from fever ; the fatal form of the latter disease, known as *kalá-ázár*, seems to be gradually disappearing from the Province. No large sanitary work was carried out during the year ; but in rural circles the improvement of the water-supplies, more especially, received much attention.

24th April, 1902.

No. 8.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Madras for 1900.

As in the previous year, the Reports of the Sanitary Board, of the Sanitary Commissioner, and of the Sanitary Engineer are published together in the same volume. The first of these three is the only one which has been curtailed in accordance with the instructions of the Government of India. These instructions did not reach the officers who prepared the other two in time to admit of their being carried into effect.

2. The total rainfall of the year exceeded that of the previous year by 7·57 inches; but was less than the average for the ten years ending 1897. The rise in the price of food grains, which began towards the end of the preceding year, became more marked in the year under review. The price of the staple food grains of each district, of the Presidency in general, verged on the famine rate and this rate was actually reached in five districts. On page 13 of the Report a table is given showing, in two selected districts, the close relation in which high prices of the chief food grains and high death-rates stand to each other.

3. Whilst the birth-rate, which was chiefly influenced by the conditions prevailing during the previous year, rose to 31·8 per thousand of the census population, and was the highest on record, the death-rate, mainly owing to increased mortality from cholera and fever, rose from 20·1 in the previous year to 23·4. Both the birth and death rates recorded are still, doubtless, much below the actual rates, owing to defective registration. But a reference to the table in paragraph 13 will show that, in the case of births more particularly, a marked improvement has been effected in registration since 1892, when the birth-rate recorded was only 25·1 as compared with 31·8 in the year under review. The death-rates recorded in four districts were under 20 per *mille* of population. Such figures only show how backward registration still is in certain parts of the Presidency. Towards the close of the year, registration of vital statistics was made compulsory in about 400 villages. In the 61 municipalities of the Presidency the birth-rate recorded was 38·5, and the death-rate 34·4; the former being 6·7 and the latter 11·0 in excess of the provincial rate. These figures need not be taken as conclusive proof that fecundity and mortality are greater in towns than in the country; but rather as indicating that registration of vital statistics is more efficiently carried out in the former than in the latter. As a matter of fact, the birth-rate of rural populations is usually higher than that of urban populations, and probably would be found to be so in Madras, as elsewhere, were registration of births effected with the same accuracy in the country as in the towns. A provincial death-rate of only 149·2 recorded for children under one year of age, supports the Sanitary Commissioner's conclusion that "one cause of deficient death-rate is certainly a tendency to ignore the deaths of infants below one year of age." The recorded infantile death-rate for the municipalities during the year under report was 223·3; and even this, although greatly higher than the rate recorded for rural areas, is probably considerably less than the actual rate.

4. *Chief Diseases.—Cholera* was credited with 60,662 deaths, or rather more than twice as many as in the previous year. The inhabitants of town circles suffered more severely than the rural population, although it might be presumed that more attention would be given to the protection of the water-supply in towns than in country villages. The death-rate from cholera in town circles was 2·8, and in rural circles 1·8, according to the return on page 68, Appendix D., of the Report. It is stated that permanganate of potash, used as a means for purifying contaminated sources of water-supply, continues to be favourably reported on by medical officers. Experiments conducted on scientific principles are required to demonstrate the specific action of this chemical in disinfecting wells contaminated with the cholera poison. Although many medical officers have a conviction that cholera outbreaks are cut short, or modified, by the disinfection of the water-supplies by the permanganate of potash, there are others who maintain that the evidence in proof of this conviction is insufficient. It is important that the question should, if possible, be definitely settled.

5. *Small-pox* was more fatal than in the preceding year, accounting for 27,692 deaths, against 16,991 in 1899. Of the total number of deaths, 8,249 were those of infants under one year of age. The Sanitary Commissioner thinks the mortality from small-pox amongst infants "cannot be minimised without having recourse to legislation. Until vaccination is made compulsory in rural areas, more satisfactory results cannot be hoped for." It may be a question whether the advantages which would result from compulsory vaccination would compensate for the abuses to which its introduction might lead. Certain, however, it is that the death-rate from small-pox was three times greater in the country than in the towns. Vaccination made good progress during 1900–01. The numbers vaccinated and re-vaccinated exceeded those of the previous year by nearly one hundred thousand. This increase, although partly due to an increase of 20 in the number of vaccinators, was mostly the result of the greater amount of work performed by each vaccinator. Whilst in the previous year the number of operations performed by each vaccinator was 1,375, in the year under review it was 1,473, according to Statement No. 1 of the Appendix to the Vaccination Report. An unfavourable feature of vaccination in Madras is the low proportion of children under one year of age successfully vaccinated. Whilst in the Madras Presidency only 348,774 children under one year of age were successfully vaccinated out of a total of 1,044,250 persons of all ages, the number in the neighbouring Presidency of Bombay was 405,584 out of a total of 532,138 of all ages. The superiority of calf-to-arm vaccination over vaccination with calf lymph preserved by admixture with glycerine, or lanoline, is still very marked. Whilst lymph taken direct from the calf and applied direct to the arm gave a percentage of 98·8 successful cases, glycerinated lymph gave a percentage of only 91·5, and lanoline lymph a percentage varying from 88·5 to 93·4.

6. The mortality recorded under the headings of *fever*, *dysentery* and *diarrhœa* was greater than in the preceding year. The Sanitary Commissioner remarks that the low death-rates ascribed to fevers in plague-infected localities were probably due to a large proportion of the deaths from fever having been entered under the heading "other causes," to avoid the inquiry as to the cause of death, consequent on a report of "fever."

7. During the year the total number of attacks from *plague* throughout the Presidency was 895, of which 665 proved fatal; figures which appear to show that the system of passports, observation, and railway inspection has, so far, been effectual in checking the general spread of the disease in the Madras Presidency.

8. The scheme for training a sufficient number of certificated sanitary inspectors for employment by municipalities and district boards is one which might be adopted with advantage in other provinces. Already, of this class of men 16 are employed by district boards and 108 by municipalities. During the year, 51 men passed the practical and theoretical examination, after training in the Medical College; so that there is now available a total of 322 men holding certificates. This scheme for the training of a sufficient staff of sanitary inspectors is one of much promise; probably no other of equal practical importance to sanitary progress in India has in recent years been devised and carried into effect.

9. *Summary.*—The year was one of high prices of food grains, a condition shown to be closely related to the death-rate. The rainfall, whilst much in excess of that for the previous year, was still below the average for the ten years ending 1897. The birth-rate was the highest hitherto recorded for the Presidency, a circumstance probably due, in part at least, to the improvement which is steadily taking place in the registration of vital statistics. The death-rate was considerably higher than in the previous year; this was probably in part due to the hard times consequent upon high prices of food, and also, in part, to improved registration. The return of death-rates of less than 20 per thousand of population in several districts shows that much still remains to be done before a reliable record of mortality can everywhere be secured. Cholera accounted for twice as many deaths as in the previous year. Permanganate of potash is considered by medical officers to have been beneficially employed in the disinfection of wells during cholera outbreaks. It would be useful to have the specific effect of the permanganate of potash in the disinfection of water containing the cholera poison definitely demonstrated by a series of scientifically conducted experiments. Small-pox was more prevalent than in the preceding year. The number of persons vaccinated shows an increase of nearly a hundred thousand over the number for 1899–1900. Plague made little progress during the year, accounting for only 665 deaths throughout the Presidency. The scheme for training a staff of sanitary inspectors for employment in the Presidency is being successfully carried out, and is likely to have an important influence on sanitary progress.

24th April, 1902.

No. 9.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bombay for 1900.

Barely had the Bombay Presidency recovered from the effects of the famine of 1896–97, when failure of the rains of 1899 led to a still more disastrous famine in the year under review. Although famine had begun to prevail before the end of 1899, it was not until the year under report that its effects came to be fully shown in the records of mortality. In its train came pestilence: plague, cholera, and fever carried off in great numbers a population enfeebled by scarcity. Subtracting the recorded number of births from the recorded number of deaths, the population is shown to have undergone, during the year, a diminution of 813,121. In other words, the deaths exceeded the births by this number. As remarked in the Government review of the Report, the year was the most unhealthy in the recent history of the Presidency.

2. A comparison is drawn between the population numbers ascertained by the recent census of 1901 and the numbers obtained by adding to the previous census numbers of 1891 the births registered since that year, and deducting from the total the deaths registered during the same period. Estimated according to this latter method, the population at the beginning of 1901 should have numbered 18,615,497, whereas the census just taken shows it to be 18,524,640. The approximation between the two sets of figures is fairly close, in spite of the fact that a detailed comparison shows wide divergences between the estimated and census population numbers in some of the collectorates. Notwithstanding these divergences, the result testifies to the general efficiency with which the registration of vital statistics was carried out during the past inter-censal ten years.

3. The small European and Eurasian population return, as usual, low birth and death rates. The death-rate, which among Europeans was only 12·5 per thousand in 1899, rose in the year under report to 20·1; whilst among Eurasians it rose at the same time from 21·72 to 28·9, showing that these two communities, although probably mostly above the reach of the famine conditions which directly or indirectly led to so high a rate of mortality amongst the native population, suffered nevertheless from the prevailing unhealthiness of the year.

4. The *birth-rate* recorded for the general population of the Presidency was 26·87 per thousand, the lowest for any of the past ten years. An examination of the table, given in paragraph 3 of the Report, will show that during the first five months of the year the birth-rate diverged but little from the average rate for the years 1890–99. This was only what was to be expected. Nine months prior

to each of the first five of 1900, scarcity had not begun to make itself felt, and the number of conceptions continued normal; but when the failure of the monsoon was followed by failure of the crops in the last months of the previous year, and famine had declared itself, the number of conceptions rapidly fell off. The table referred to shows that the number of births in each of the last seven months of the year under report was greatly below the average for the corresponding month of the previous ten-year period. The ninth month preceding each of the months returning a low birth-rate was one of severe famine; diminished fecundity kept pace with the progress of the famine. For the year as a whole the number of births was exceeded by the number of deaths in all except four districts of the Presidency. The percentage of children still-born to children born alive continues, as hitherto, to be very high in the city of Bombay. Whilst for the Presidency as a whole this percentage was only 1·66, in Bombay city it was recorded to be 16·46. But there are good reasons for believing that the registration of births is very defective in the latter. It is stated that still-births are unusually common in Kánara, and that this is "due to well known climatic causes." We do not recollect to have seen these climatic causes described.

5. The *death-rate* of 70·07 is almost exactly double that for the previous year, and considerably more than double the mean ratio for the previous five years. The Sanitary Commissioner is no doubt correct when he says, "This result is chiefly due to famine." Where, as in the Gujarat districts, the famine was most severe, there the mortality rate was also great. But in the Gujarat districts the enormous death-rate recorded was largely swollen by the tide of immigrants from adjacent Native States. The Deputy Sanitary Commissioner of the Gujarat Registration Circle "is inclined to attribute one-third of the total deaths to immigrants." To the same cause, the influx into them of famine-stricken people, was due the abnormally high death-rate in towns. Whilst the rural circles record a death-rate of 65·57, the urban circles record a death-rate of 102·33. Each of the specified causes of death, except plague, contributed to the increased mortality of the year.

6. *Cholera* accounted for no fewer than 163,889 deaths, and yet, as stated in the Government review of the Report, "there can be no doubt that the record is largely defective, and that the actual mortality from this cause was much higher." The ratio of deaths, per thousand of population, attributed to cholera was 8·71 as compared with a mean ratio of 1·75 for the previous five years. The disease was widely diffused over the Province: of the 220 rural circles only 18 enjoyed entire immunity from attack, and of the 56 town circles only five. Six pages of the Report are devoted to a history of the epidemic, but without throwing much light on the causes which led to widespread and fatal prevalence of the disease. An examination of the progress of the epidemic month by month shows that, as usual, the coldest months were those in which the disease was least fatal. In the four months January, February, November, December, only 2,676 cholera deaths were registered out of the total for the year of 163,889. From March the mortality increased until it reached its maximum of 44,521 deaths in July, after which it rapidly decreased. It has repeatedly been demonstrated that there is no necessary connection between cholera and famine, although when an outbreak occurs people enfeebled by want naturally offer less resistance to this, or to any other disease, than those in vigorous health. A perusal of the report leads to the same conclusion as that arrived at by the Deputy Sanitary Commissioner, Southern Registration District, as the result of his observation of the disease during the year. He writes: "No fresh light has been thrown on the causes of the disease in affected localities." The Deputy Sanitary Commissioner of the Gujarat Registration District, which suffered more severely than any other, expresses himself in somewhat similar terms. "It is impossible," he says, "to trace the origin of the outbreak. Imported, no doubt it was, but from whence or by what agency it was impossible to ascertain." On the other hand, there are some statements made by the Sanitary Commissioner which might lead to the belief that the origin of the outbreaks of cholera in particular localities had been ascertained with certainty. For example, regarding the death-rate we read in paragraph 42: "Ahmedabad cantonment was also in a famine district, but the increase is due to an outbreak of cholera owing to the drinking of impure river water." And again in paragraph 131: "It was in many cases impossible to prevent workers taking water from unauthorised sources, or bringing in unwholesome food, and so starting cholera, which, when it broke out, caused the people to scatter and infect other places." Unsupported by proof such statements do not, however, carry much weight.

7. The mortality from *small-pox* was the highest recorded for any one of the past ten years, but cannot be said to be excessive. The ratio of deaths per thousand of population due to this disease was 0·52, as compared with an average ratio of 0·12 for the previous five years. To the abnormal conditions which prevailed in the Province during the year a large part of the increased small-pox mortality was doubtless due. Not only was the work of vaccination seriously interfered with by the diversion from their own special duties of members of the vaccination establishment in consequence of the need for their employment in connection with famine relief measures, but the enormous influx of starving immigrants from Native States contributed, in some parts of the country, materially to swell the death-rate from small-pox. In the numbers vaccinated during the year there was a decrease of no less than 108,350 compared with the numbers for the previous year, a result partly due to the diminished number of births consequent upon the severe and widespread famine from which the Province suffered. The percentage of successful cases, excluding those "unknown," was 98·76, and cannot be regarded otherwise than as satisfactory. In re-vaccination the percentage of success recorded was 83·11. In spite of the adverse circumstances under which vaccination had to be carried on during the year, it is satisfactory to note that the number of infants successfully vaccinated in the Presidency "represents almost all the children available for vaccination." No better testimony to the efficient working of the Vaccination Department of a province could be offered.

8. Under the heading of *fever*, over half a million deaths were registered, or more than double the number registered in the previous year. The death-rate per thousand of population from this cause was 28·87, as compared with 12·14 in 1899. In the Gujarat Registration District the mortality from fever was excessive, a death-rate of 111·27 being recorded in one collectorate and of 167·77 in another. These figures must, however, be accepted with some reservation. The Sanitary Commissioner says:

"The returns from these two districts show serious defects in registration, and fever as a cause of death is much too frequently entered. The highest recorded number of deaths from fever in any month was in May, which is a very unusual occurrence, and may be partly accounted for by the fact that in this month also the cholera epidemic reached its greatest virulence, and many deaths from cholera were entered under the head of *fever*."

9. The number of deaths from *plague*, which in the previous year was 96,596, decreased to 33,196. As stated in the Government review of the Report, "these figures are very satisfactory"; but the subsequent history of the disease will show that any hopes founded on them of an early cessation of the epidemic would have been delusive. The returns bring out very clearly that the inhabitants of towns were the chief sufferers. Bombay city recorded 13,285 deaths, Poona 4,325, Belgaum 1,247, and Nasik 1,224, or between them 20,061; whilst the total for all the towns amounted to 22,087, leaving only 11,109 to be accounted for throughout the rest of the province.

10. That in such a year of distress the mortality from diarrhoea and dysentery would be great was only to be expected. The deaths from these diseases increased from 74,738 in the previous year to 218,243 in the year under report. The diseases, writes the Deputy Sanitary Commissioner of the Gujarat Registration District, "were most prevalent during and just after the rains, when damp and chills were added to the chief cause—unsuitable food." The same Officer adds, "The consumption of badly-cooked, half-cooked or raw grain, wild seeds, leaves, bark of trees, roots, &c., in fact, of almost anything solid which would help to fill the void; these are the chief causes of what was really an epidemic of dysentery and diarrhœa."

11. In last year's memorandum we commented upon the increase since 1896 in the number of deaths returned under the heading of *other causes*. This increase has continued during the year under report. From 100,112 in 1896, the number has now reached 342,027. Last year the number was 254,872; but as the total number of deaths from all causes in that year was only 672,289 as compared with 1,318,783 in the year under review, it is evident that the *proportion* of deaths registered under the head of "other causes" during 1900 has not only not increased but has greatly decreased. Had they been in the same proportion to the total deaths as in the preceding year, their number would have exceeded the recorded number by more than a third. This marked decrease in the proportion of deaths registered under the head of "other causes" in the year under review coincides, it will be observed, with a still more marked decrease in the number of deaths attributed to plague. In our previous memorandum on the Sanitary Report for the Bombay Presidency, it was suggested that the prevalence of plague might induce people to report deaths really due to fever as having resulted from "other causes," so as to avoid the troublesome inquiries which the report of an unusual number of deaths from fever might give rise to, fever being a prominent symptom of plague, and therefore likely to arouse suspicion and lead to search being made for cases of the latter disease. The decrease of plague mortality during the year may, on this hypothesis, have been indirectly connected with the decrease in the proportion of deaths registered under the head of "other causes."

12. In the year when the resources of the Province were being strained to the utmost in the combat with famine and pestilence, it was not to be expected that funds would be available for the prosecution of extensive sanitary works. In the words of the Government review of the Report:—"Owing to plague and famine local bodies were unable during the year to take up any projects of importance for the improvement of their sanitary arrangements."

13. The continued efficiency with which the duties of Port Health Officer were discharged during the year receives practical testimony from the fact that, although there were unfortunately outbreaks of plague at foreign ports, in no instance could these be traced to the crew or passengers on vessels from Bombay. Not plague alone, but epidemics of cholera and small-pox prevailed during the year, throwing on the Port Health Officer and his staff an unusual burden of work and responsibility. Besides the 13,286 deaths from plague, there were 4,273 from cholera and 3,018 from small-pox recorded in Bombay City during the year.

14. *Summary.*—The year was the most unhealthy in the recent history of the Presidency. Famine and pestilence caused excessive mortality, whilst the birth-rate was the lowest on record in any of the preceding ten years. The number of deaths exceeded the number of births by more than three-quarters of a million. In some parts of the country the death-rate was swelled by the large influx of starving people from the neighbouring Native States. An epidemic of cholera swept off 163,889 people; and it is believed that the actual mortality from this cause was even greater. Small-pox, although more fatal than in any year of the previous ten, was responsible for a death-rate of only 0·52 per thousand of population. It was only to be expected that in such a year the progress of vaccination would receive a check; the numbers vaccinated show a decrease, as compared with those for the preceding year, of upwards of a hundred thousand. Dysentery and diarrhœa were excessively fatal. Plague was the only disease which showed a substantial abatement. The *proportion* of deaths registered under the head of "other causes" was less than in the previous year, although the actual number was greater. The funds, which in a normal year would have been available for sanitary works, were swallowed up in the expenditure necessitated by the combat with plague and famine. Epidemics of plague, cholera, and small-pox in Bombay City threw a heavy burden of work and responsibility on the Port Health Officer and his staff. The measures adopted for preventing the spread of plague and other communicable diseases by ships proved eminently successful.

24th April, 1902.

No. 10.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner for the Hyderabad Assigned Districts for 1900.

Judged by its record of mortality, the year was the most unhealthy of any of the thirty years which preceded it. The death-rate was largely influenced by the severe famine from which the Province suffered throughout 1900. *Jowari*, the staple food grain of the people, which could be bought in the previous year at the average price of almost 23 seers per rupee, cost during the year under review a rupee for less than 10 seers, or considerably more than double. For 1899 a rainfall of only 12·92 inches was recorded, against 33·07 for the year under report. The failure of the rains in the former year was the cause of the severe famine in the latter.

2. It is stated that increased attention was given to the registration of vital statistics during the year. An examination of Table I., page 2, of the Report, reveals remarkable differences in the proportion per cent. of the registers found to be defective by the several inspecting agencies. Of the registers examined by Deputy Commissioners, a percentage of 1·5 only was found to be defective; whilst of those examined by District Superintendents of Police the percentage was 5·8; and of those by Civil Surgeons 9·6. Such wide differences would suggest that the same method of testing the accuracy of the registers is not followed by the different inspecting officers. The Sanitary Commissioner writes:—"I myself inspected 152 registers during the year, and found no omission." The nature of the inspection to which these 152 registers were subjected is not stated. If a house-to-house inquiry was made, and the births and deaths thus ascertained were compared with the entries of births and deaths in the registers, the result of this inspection would bear striking testimony to the completeness with which the registration of vital statistics is effected in Berar. It is only by a comparison of the entries of births and deaths in the registers with the births and deaths ascertained by a house-to-house inquiry that inaccuracies can, with any approach to certainty, be detected. If thoroughly carried out, this method of inspection necessitates much patient labour, and an expenditure of time which hard-worked officers, with other pressing duties, can ill spare. The Resident realises its importance, and "is glad to hear of the institution of house-to-house inquiry by inspecting officers in some districts, and hopes that it will be extended to all at a very early date."

3. The *birth-rate* fell from 50·5 per thousand of population in the previous year to 31·3 in the year under review. As the former was the highest rate on record for the Province, so we have to go back to the early seventies, when registration was less reliable than it is now, to find a lower birth-rate than that recorded for 1900. As the exceptionally high birth-rate of 1899 was the normal sequence of the conditions of prosperity and exceptional healthiness of the year immediately preceding it, so the exceptionally low birth-rate of the year under report followed the failure of the rains and crops in the last half of 1899 and the conditions of severe famine which ensued. "The low rates," writes the Resident, "was of course the result of the famine and its accompaniments."

4. The *death-rate* of 82·7 for the year was the highest on record, within the period for which trustworthy vital statistics are available. In 1878, under somewhat similar conditions of famine, the death-rate closely approximated to that of the year under report. It was then 81·5 per thousand of population. The Sanitary Commissioner succinctly sums up the causes of the excessive death-rate recorded for the year under report. These were, the severe famine which prevailed throughout the the year, the high birth-rate of the preceding year, the influx of starving people from the neighbouring Native State of Hyderabad, and an epidemic of cholera. The first of these, the severe and prolonged famine, was the principal cause of the excessive mortality of the year; the others were subsidiary and to some extent, at least, dependent upon it. The high birth-rate of its predecessor helped to raise the death-rate of the year under report by adding to the population an unusually great number of those most liable to death. The death-rate amongst children under one year of age was 478·5 per thousand, a proportion vastly in excess of that during any subsequent year of life. From this it is evident that the death-rate would usually vary with the proportion which the number of children under one year of age in the population bore to the total population. The third cause assigned by the Sanitary Commissioner for the increased mortality of the year, the influx into Berar of starving people from beyond its borders, would have the effect of raising the recorded above the real death-rate of the Province by the inclusion in the returns of deaths of persons not belonging to the provincial population. Examples are given showing the effect which this factor exercised in raising the death-rate of towns of the Province close to the borders of the Hyderabad State. In one of these towns, Pushad, the death-rate was swollen by the influx of starving people from Hyderabad territory to no less than 251·7 per thousand of its census population numbers.

5. *History of Chief Diseases.*—A severe epidemic of *cholera* accounted for 18,375 deaths, a number only three times exceeded in any of the previous 30 years. The Province enjoyed complete immunity from cholera during 1898 and until August of the following year, when cases began to occur. In January of the year under review the deaths attributed to it numbered 267; and from this time onward, except during March, when there was a temporary check in its progress, the mortality from cholera rapidly increased month by month until it attained its maximum in July. After this the mortality quickly decreased; in October only five deaths from cholera were registered; and in the last two months of the year, none. The epidemic was a continuation of the outbreak which began in August of the preceding year; and regarding the cause, or causes, of this outbreak nothing definite is known. The Sanitary Commissioner says that permanganate of potash was found to be "most invaluable in dealing with the cholera epidemic. As soon as cholera was reported from a village, a hospital assistant, if available, if not, a vaccinator, was at once sent off to the infected village with orders to disinfect all the water supply, and four or five days after the water supply had been disinfected the epidemic in almost every case ceased. This disinfection of wells answered admirably, and one was pretty certain to check an epidemic by it when the village water supply was

A. GODLEY,
Under Secretary of State for India.

INDIA OFFICE,
November, 1903.

REPORT.

The present Report on Sanitary Measures in India during the year 1901 is prepared for presentation to Parliament. It contains chapters on the health of the European and Native troops, on the health of prisoners in jails, and on the health of the general population ; it also contains chapters on vaccination, on medical institutions, including medical schools and lunatic asylums, and a chapter on sanitary works. Appended to the Report are abstracts of reports by the three principal Sanitary Commissioners in India, and memoranda by the Army Sanitary Commission in England reviewing the several Sanitary Reports for India.

I.—EUROPEAN ARMY.

Sickness and mortality in 1901.

The health of the European troops serving in India during 1901 was on the whole good ; the admission, daily sick and death-rates were the lowest recorded for many years, but the invaliding ratio was higher. On an average strength of 60,838, the admissions into hospital were in the ratio of 1,104 per 1,000, against 1,143 in 1900, the daily sick-rate fell from 72 to 67, and the death-rate from 14·62 to 12·38. The invaliding ratio (39) was higher by 6 per 1,000, so that the total loss by death and invaliding was equal to 51 per 1,000, an increase of 3 per 1,000 on the previous year.

The following statement shows the relative extent of sickness and mortality among European troops in the four Commands during 1901 and the previous year :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.				
			Admissions.	Daily Sick.	Deaths.	Invaliding.	Total Loss.
Bengal	1901	19,000	980	62	12·95	37	50
	1900	18,956	1,075	70	13·40	33	46
Punjab	1901	16,431	1,090	63	12·90	38	51
	1900	16,562	1,085	65	12·62	27	40
Madras	1901	10,282	1,278	79	9·34	43	52
	1900	9,984	1,268	82	16·53	46	63
Bombay ...	1901	15,125	1,140	69	13·16	42	55
	1900	15,051	1,211	75	17·08	33	50
INDIA ...	1901	60,838	1,104	67	12·38	39	51
	1900	60,553	1,143	72	14·62	33	48

It will be seen from the above statement that Madras was the most unhealthy of the four Commands, Bombay coming next, though both compare favourably with the previous year. In regard to mortality, there was an improvement in all Commands except the Punjab, the decrease being most marked in Madras, where the death-rate fell from 16·53 to 9·34.

The chief causes of sickness in the whole European Army were, as usual, intermittent fever and venereal diseases, the former yielding a ratio of 293 per 1,000 against 308 in 1900, and the latter 276 per 1,000 against 298. More than a half (52 per cent.) of the total sickness resulted from these two causes. Enteric fever, as usual, was the chief cause of mortality, the death-rate from it being 3·32, which however is an improvement on 4·77, the ratio of the previous year. Twenty-seven per cent. of the total deaths were due to this cause.

Groups of stations.—The following table shows the sickness and mortality among the European troops according to groups :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,049	1,273	67	7·63
Burma Inland	1,906	1,672	97	13·12
Bengal and Orissa	2,025	1,139	75	23·70
Gangetic Plain and Chutia-Nagpur	6,160	938	58	13·31
Upper Sub-Himalayan	11,045	1,179	69	14·67
North-Western Frontier, Indus Valley, and North-Western Rajputana.	4,458	1,041	62	10·09
South-Eastern Rajputana, Central India, and Gujarat.	5,442	1,412	85	16·72
Deccan	8,630	1,203	79	11·94
Western Coast	1,552	831	54	5·15
Southern India	2,662	1,063	59	6·39
Hill Stations	8,692	781	49	8·63
Hill Convalescent Depôts and Sanitaria ...	3,184	1,303	81	13·51

Of the above 12 groups, six returned a higher daily sick-rate than that for the European Army as a whole, and in six groups the death-rate was greater. The most unhealthy groups, judged by the daily sick-rate, were Burma Inland and Central India, with daily sick-rates of 97 and 85 per 1,000 respectively.

Of the stations with a strength of over 1,000, the highest death-rates were those of Ferozepore (25·00), Umballa (20·42), Meerut (16·42), Peshawar (15·57), Allahabad (13·64), and Mhow (13·64).

Cholera.—There was very little cholera among the European troops, only 12 cases, all of which were fatal, having been recorded during the year, against 107 cases and 88 deaths in 1900.

Small-pox.—Among the whole of the European troops in India there were during the year under notice 20 cases of small-pox with three deaths. In the previous year there were 36 cases and three deaths.

Fevers.—From intermittent fever the admissions to hospital among the European troops in 1901 were in the ratio of 293 per 1,000 of strength, against 308 in the previous year. The death-rate was also lower, viz., 0·36 per 1,000, against 0·66 in 1900.

There was a further satisfactory decrease in the prevalence of enteric fever during the year. The admissions fell from 970 or 16·0 per 1,000 of strength to 776 or 12·8, which is the lowest recorded since 1887, and the deaths from 289 or 4·77 per 1,000 to 202 or 3·32. The decrease is attributed chiefly to the increased age of the average soldier, and his greater length of Indian service, due to the cessation of the usual reliefs and to the retention in the country of time-expired men. The reduction would also appear to be due to the greater care taken with regard to soldiers' food, drink, and sanitary surroundings, and to the absence of field service ; but it remains to be seen what effect the arrival of large drafts of young soldiers will have on the prevalence of the disease. Of the four Commands the Punjab recorded the highest mortality under this head, viz., 4·99, followed by Bombay 3·50, Bengal 2·58, and Madras 1·75. Among the larger stations with an average strength of over 1,000, Ferozepore returned a death-rate from this fever of 13·46, Peshawar 8·72, Umballa 8·17, Meerut 6·32, Quetta 4·09, Mhow 4·28, Secunderabad 3·77, and Lucknow 3·43. As usual, young and unacclimatised soldiers were the chief sufferers; among those from 20 to 25 years of age the death-rate was 4·91 per 1,000 against 6·85 in 1900, while among men between 25 and 30, and from 30 to

35, the mortality was 2·71 and 2·18 per 1,000 respectively. Among men of less than one year's residence in India the death-rate from this fever was 6·90 per 1,000, among men between one and two years 3·48, and among men between five and ten years' service 2·22 per 1,000. Of the total 202 deaths from enteric fever, 57 per cent. occurred among men between the ages of 20–25, and 35 per cent. among men between the ages of 25–30.

Bowel Complaints.—The admissions from dysentery and diarrhœa among the European troops were in the ratio of 35 per 1,000 of strength, or 9 per 1,000 more than in 1900. The mortality from dysentery was in the ratio of 0·97 against 0·86 in the previous year, and from diarrhœa 0·02 against 0·05. Dysentery was most prevalent, as usual, in the Bengal-Orissa group, but it was more prevalent in the Madras Command than in that of Bengal, though not so fatal.

Abscess of the Liver.—From abscess of the liver there were 101 deaths, giving a ratio of 1·36 per 1,000 of strength, against 94 or 1·57 in 1900.

Plague.—There were only three cases of plague among the European troops, and one death, against six cases and one death in 1900.

Venereal Diseases.—Venereal diseases ranked second in the list of causes of admission to hospital, and first in the causes of invaliding. They were the cause of 25 per cent. of the total sickness during 1901, and of 16 per cent. of the invaliding of the European Army of India. The admission-rate from venereal diseases per 1,000 of strength was 276·0, being 22·1 lower than in 1900 and 246·3 below the maximum rate (522·3) recorded in 1895. Various causes have been at work in bringing about this great reduction in the prevalence of these diseases, the chief being the increased age and experience of the men ; other causes have been the successful working of the cantonment general hospitals, the interest taken in the matter by regimental and other authorities, and lectures and warnings by medical officers, chaplains, and regimental officers. All the Commands shared in the decrease except Madras, where the ratio rose from 354·4 to 372·8 ; Bombay followed with 282·6, against 327·0 in 1900 ; Bengal 258·8, against 299·9 ; and the Punjab 229·1, against 235·8. The number of men constantly sick in hospital from these diseases was 1,416, against 1,630 in the previous year ; and the average stay of a case in hospital was about 31 days. The deaths from these diseases numbered eight, and the invalidings 383, against 14 and 380 respectively in 1900.

Invaliding.—The loss to the whole army by invaliding during 1901 amounted to 2,393 men, equal to 39·32 per 1,000, against 2,026 or 33·46 in 1900. The proportion of invalids to strength was as usual highest in the Madras Command (42·60), followed by Bombay (41·92), the Punjab (37·67), and Bengal (36·95). As regards the influence of age and length of residence in India upon invaliding, 42 per cent. of the total number invalided were under 25 years of age, against 52 per cent. in 1900, while 14 per cent. against 33 were of less than two years' service, and 60 per cent. against 72 were of less than five years' service.

II.—NATIVE ARMY.

Sickness and Mortality in 1901.—The health of the Native Army of India was on the whole also better than in 1900.

The ratios of sickness and mortality among Native troops in the five Commands during 1901 and the previous year are given in the following table :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.		
			Admissions.	Daily Sick.	Deaths.
Bengal	1901	26,200	667	27	8·44
	1900	26,582	717	31	10·46
Punjab	1901	46,050	944	30	12·03
	1900	42,311	796	28	14·72
Madras	1901	18,022	697	28	8·80
	1900	20,407	690	30	12·69
Bombay	1901	22,428	933	35	12·93
	1900	24,908	957	35	18·71
Hyderabad Contingent	1901	5,826	543	21	4·81
	1900	6,260	561	22	12·62
INDIA	1901	122,806	829	30	10·68
	1900	123,463	785	30	14·04

Of the five Commands, Bombay was again the most unhealthy in 1901, though its death-rate of 12·93 per 1,000 was nearly 6 per 1,000 lower than in the previous year ; the Punjab returned the next highest mortality of 12·03. Pneumonia continued very prevalent in these two Commands, and the death-rates from it were 4·01 and 3·87 per 1,000 respectively.

The chief cause of sickness in the Native Army was ague, which caused 43 per cent. of the total admissions. Among the diseases from which the admissions to hospital were higher than in 1900 were influenza, malarial fever and respiratory diseases ; while from cholera, enteric fever, bowel complaints and venereal disease there was a decrease in the admissions. From cholera the admission-rate fell from 5·2 per 1,000 of average strength in 1900 to 0·3, and from venereal diseases from 42·5 to 34·3, as compared with 276·0 per 1,000 among European troops. There were 8 deaths and 128 invalidings from venereal disease, against 8 deaths and 383 invalidings among European troops.

Pneumonia was the chief cause of death in the Native Army, and contributed 25 per cent. of the total deaths, the death-rate being 2·72 per 1,000 of average strength, against 3·32 in 1900. From this disease the mortality among the Native soldiers was nearly five times as great as that among European troops (0·56 per 1,000). Fevers of all kinds were the cause of 14 per cent. of the total deaths, against 29 per cent. among the European troops. From ague, remittent and simple continued fevers, the deaths among the Native troops were in the ratio of 2·26 per 1,000, while among the European troops the proportion was 0·58. On the other hand, the death-rate from enteric fever among the Native troops was only 0·12 per 1,000, as compared with 3·32 among the European troops.

From cholera there were only 19 deaths in the Native Army, equal to 0·15 per 1,000 of strength, as compared with 390 or 3·16 in 1900.

During 1901 there were 70 cases of plague among the Native troops with 41 deaths, against 56 cases and 29 deaths in 1900.

Groups of stations.—The following statement gives the principal statistics of the Native Army, arranged in geographical groups, for 1901 :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,452	545	26	13·09
Burma, Inland	4,084	1,214	35	9·06
Assam	1,472	1,082	46	5·43
Bengal and Orissa	2,287	852	42	11·81
Gangetic Plain and Chutia-Nagpur	5,564	625	26	12·58
Upper Sub-Himalayan	15,263	657	25	9·37
North-Western Frontier, Indus Valley, and North-Western Rajputana.	16,051	957	32	10·09
South-Eastern Rajputana, Central India, and Gujarat.	10,994	1,024	37	11·46
Deccan	14,468	602	26	6·22
Western Coast	2,021	842	33	14·84
Southern India	6,436	655	32	10·25
Hill Stations	20,936	945	35	15·19

In eight of the 12 groups the daily sick-rate was higher than that for the whole Native Army, and in six the mortality was greater. The highest mortality was recorded by the Hill Stations group, viz., 15·19, of which pneumonia and other respiratory diseases contributed 5·35. In 1900 this group returned a death-rate of 15·39.

Of the large stations with a strength of over 1,000, the following recorded the highest death-rates :—Bombay 21·36, Meean Meer 20·75, Dera Ismail Khan 16·09, Edwardesabad 14·30, Abbottabad 13·28, and Bakloh 12·94. In the first four stations pneumonia was the chief cause of death and in the other two tubercle of the lungs.

III.—GENERAL POPULATION.

The year 1901 was hotter and slightly drier than usual, and the rainfall was scanty and unevenly distributed. Actual famine was present only in Gujarat and the Deccan, and there was an improvement in the health of the general population as compared with the previous year.

The third general census of India was taken on the 1st of March in the year under notice, the result being an increase of 4·4 per cent. in British India over the population of 1891, and a corresponding decrease in Native States. Registration of vital statistics is improving, though improvement is by no means uniform, and the statistics must still be regarded as possessing only comparative value. In 1901 the birth-rates of the several provinces varied between 41·35 per 1,000 of population in the United Provinces of Agra and Oudh and 18·83 in Coorg, and the death-rates between 37·12 in Bombay Presidency and 19·16 in the North-West Frontier province. Of the chief diseases cholera showed a remarkable abatement, and the deaths fell from 804,378 in 1900 to 271,210. No province was quite free from the disease, but in all the provinces except Madras and Coorg the mortality was lower than in the previous year. The highest ratios under this head were 2·2 in Madras, 1·48 in Bengal, 1·42 in Assam, and 1·13 in the United Provinces. The mortality from small-pox was about the same as in 1900, the deaths numbering nearly 90,000. The fever mortality was 18 per cent. below that recorded in 1900, and accounted for 63·5 per cent. of the total deaths. Dysentery and diarrhœa were much diminished, the deaths having fallen from 525,187 to 248,287. There was an increase under plague of over 67 per cent. For the whole of India the plague deaths in 1901 aggregated 234,672 and of these more than half (128,259) occurred in Bombay, Bengal coming next with 78,629 fatal cases.

The deaths from the chief diseases and from all causes in the several provinces were as follows :—

PROVINCES.	CHOLERA.		SMALL-POX.		FEVERS.		DYSENTERY AND DIARRHŒA.		DEATHS FROM ALL CAUSES.			
	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.

* The figures within brackets show the death-rate for 1900 if calculated on the 1901 census returns.

Bengal. The health of Bengal during 1901 improved, the birth-rate having increased since the previous year by 1·63, and the death-rate decreased by 3·94 per 1,000, but they still compare unfavourably with the quinquennial average. The scanty and irregular rainfall affected the agricultural outturn and these conditions are to some extent reflected in the vital statistics. The statistical data in the provincial review are based on the census of

1901. The number of births registered in the province rose from 2,749,582 or 36·94 per 1,000 of population in 1900 to 2,870,806 or 38·68, the latter being made up of district rates varying from 44·69 in Muzaffarpur to 10·76 in Calcutta. 18 other districts had rates exceeding 40 per 1,000 while in 17 districts, in many of which the prices of food grains during 1900 were very high, the birth-rate was lower than in the previous year. In all the districts but four the birth-rate was over 30 per 1,000. The divisional statistics for 1901 are satisfactory, the birth-rate being higher and the mortality lower in every division of the province except Burdwan and Orissa. The provincial birth-rate of 38·57 is calculated from the returns of 719 registering circles of which 157 are urban and 562 rural; the former give a ratio of 22·74, the latter of 39·39 per 1,000. The birth-rate is thus considerably lower in the towns than in the rural areas as is usually the case. 10 towns recorded a birth-rate of over 40 per 1,000, the highest being 54·77 at Jamalpur, and 71 below 25 per 1,000, the lowest being Jhalokati. As a result of the general unhealthiness and the high range of prices during 1900, only 93 rural areas returned a birth-rate of over 45 per 1,000, against 107 and 247 during the two previous years.

The total number of deaths registered during the year under review was 2,310,424, or 31·04 per 1,000, as compared with 2,603,736, or 34·98 in 1900. There was thus an excess of births over deaths of 7·53 per 1,000 of population. Twenty-three towns had a death-rate above 44 per 1,000, but only 45 rural areas exceeded this figure, against 116 in 1900. The district rates ranged from 56·79 in Patna to 20·21 in Sonthal Parganas. In both urban and rural areas there was a notably decreased mortality, the ratio in the former falling from 41·14 per 1,000 to 37·12, and in the latter from 34·66 to 30·72.

From all the principal diseases, except small-pox and plague, the mortality was lower than in 1900. The severe epidemic of small-pox which lasted throughout the year was more than counterbalanced by the comparative absence of cholera. Of the four great natural divisions of the province (Bengal, Behar, Chota Nagpur and Orissa), it was only in the last-named that the incidence of the chief diseases was more severe.

Although but one district enjoyed complete immunity from cholera during the year, the disease claimed only 110,753 victims against 345,878 during the previous year, the corresponding ratios being 1·48 and 4·64 per 1,000 respectively. Except in five districts the mortality from cholera diminished; 18,806 villages were attacked, against 33,142 in 1900, and the disease assumed an epidemic form in 43 areas against 228. This marked subsidence is attributed to sufficiency of the people's food supply, and the necessity they were under of obtaining pure water for domestic purposes from rivers, instead of from their often unclean wells which the deficiency of rainfall had left dry. As measures of prevention, disinfection of wells was carried on in 12 districts with good results, and the anti-cholera inoculations, though less numerous, were effective. At Goalundo, *e.g.*, among coolies exposed to the disease, only 1·2 per cent. of those inoculated were affected and none died, while of those not inoculated 8·36 per cent. took the disease, of whom 50 per cent. died.

The mortality from small-pox was greater than it has ever been since 1877, the number of deaths rising from 20,620 or ·27 per 1,000 in 1900 to 37,680 or ·50. The disease was present in all the districts, and in 37 out of the 46 the mortality therefrom was higher than during the previous year. Cuttack (3·51), Midnapore (2·49), and Calcutta (2·47), recorded the highest death-rates, but in five other districts, including Balasore and Puri, a rate of over 1 per 1,000 was recorded. The disease was thus virulent throughout the Orissa Division. The death-rate from small-pox was higher in towns than in rural areas, being in the former 1·09 per 1,000, and in the latter ·47.

Nearly 70 per cent. of the total number of deaths were recorded under the head of fever. Prevalent in every district this disease caused 1,617,019 deaths, against 1,703,804 in 1900, the corresponding ratios being 21·72 and 22·89 per 1,000. The mortality was higher in 16 districts and lower in the rest, and the fever death-rates ranged from 35·27 in Dinajpur to 7·44 in Calcutta. In spite of the virulence of the disease there was again no increase in the sale of quinine, but on the contrary a slight decrease. The type of fever prevalent in all but 12 districts of the Province was chiefly malarial, and the cause assigned is the excessive humidity of the soil, both in the Terai districts and the low-lying lands stretching down to the sea-board.

Dysentery and diarrhœa were less prevalent than in the preceding year; 59,643 persons succumbed, against 64,664 in 1900, the corresponding ratios being ·80

and ·91. The incidence of these diseases was more severe in 10 only out of the 46 districts. Puri (5·56 per 1,000), Patna (5·06) and Howrah (4·54) recorded the highest death-rates, while Darjeeling, which in 1900 headed the list, came fourth. For three years the diseases have prevailed with the greatest intensity in the same 16 districts, the above four and Calcutta, Cuttack, Balasore, Saran, Hooghly, Dacca, Ranchi, Midnapore, 24-Parganas, Burdwan, Jalpaiguri, and Darbhanga.

Plague was increasingly rife throughout the province during the year under review, cases having been reported from every division. In six of the divisions, however, the cases were chiefly sporadic, the brunt of the disease being borne by the Patna division, where 52,998 out of the 56,190 deaths which occurred outside the towns were recorded. As in 1900, Patna, Saran and Gaya were the districts which suffered most severely. The total number of plague deaths for the whole province was 78,629, more than double the number of the previous year (38,412). Of the three methods of prevention, evacuation of houses was readily resorted to in country districts, disinfection was usually regarded with suspicion, but was carried out in some of the larger towns with good results, while inoculation was also attempted and seems to have been attended with a considerable measure of success in Gaya town.

In the municipality of Calcutta the birth-rate again fell, and for 1901 stood at 10·76 per 1,000, being much lower than in mufassal towns where it was 26·34. The registered deaths numbered 32,456 or 38·28 per 1,000 of population, against 36,709 in the previous year. There was increased mortality from small-pox (2,097 deaths, against 1,010 in 1900), but less from plague (7,883 deaths, against 8,278), and cholera (1,720 deaths, against 2,754). Infant mortality was especially heavy in Calcutta, the ratio being 48 per cent. of births.

United Provinces of Agra and Oudh

The year was a very healthy one in the United Provinces of Agra and Oudh; the birth-rate was higher than the quinquennial average, and, except in the district of Naini Tal and in certain of the towns, higher also than the death-rate. The statistical data of the year under report are based upon the census of 1901, according to which the population of the United Provinces stands at 47,691,782, the increase during the last decade being 786,991, and the yearly rate of increase 1·6 per 1,000. During the year 1,972,131 births were registered, being equal to 41·35 per 1,000, against 1,892,169 or 40·34 in 1900. Of the total 48 districts 29 exceeded and 19 fell short of the provincial average birth-rate, which was composed of rates varying from 51·28 in Hardoi to 27·81 in Dehra Dun. Ten other districts, including Moradabad (50·13), Budaun (49·93), and Shahjahanpur (48·09), returned rates of over 45, and 7 of below 35 per 1,000. The birth-rate in municipalities was 40·28 against 41·26 in the previous year, and was made up of extremes ranging from 57·90 in Pihani to 16·67 in Mussoorie.

The number of deaths recorded was 1,445,035 or 30·30 per 1,000 of population, against 1,460,139 or 31·13 in 1900. Of the districts, Benares showed the highest death-rate, viz., 40·35, while Farrukhabad, Hardoi, Bareilly, and Lucknow also exceeded 38. Gorakhpur (19·69) and four other districts returned rates of less than 23 per 1000. In municipalities the death-rate again rose from 42·75 in 1900 to 43·29, the mortality being highest in Brindaban (76·11) and Benares (74·66), both pilgrim resorts, and of 104 municipalities 35 recorded more deaths than births. Registration was again tested by the local authorities, and the result disclosed omissions of 2·40 per cent. on 317,086 births and of 1·99 per cent. on 241,983 deaths. The percentages of omissions discovered by the vaccination staff were ·46 and ·27 of births and deaths respectively. Infantile mortality has on the whole been rising during the last decade, and in the year under review stood at 232·7 per 1,000 infants born. The seasonal incidence of the total mortality closely followed that of the fever mortality, being highest in October and lowest in February.

Cholera was less prevalent than in the preceding year. The total number of deaths recorded was 53,995 or 1·13 per 1,000 against 84,960 or 1·81 in 1900. Of the districts, Hardoi showed the highest ratio, 5·33, while for the town of Sahatwar the cholera death-rate was 28·93. The heaviest mortality occurred in September and October. Treatment of the wells with permanganate of potash and the appointment of men of either caste to draw water for all from uninfected wells proved of benefit as measures of prevention.

Only 981 deaths from small-pox occurred, and the death-rate from this disease fell from 0·03 in 1900, which was itself the lowest on record, to 0·02. No high rates were anywhere recorded. The Sanitary Commissioner, Major J. Chaytor-White, I.M.S.,

observes: "the beneficial effects of vaccination were assuredly never more eloquently proved, and in this respect we can, I venture to think, compare favourably with many European communities."

The mortality from fever was slightly heavier than in the previous year, 1,118,977 deaths being returned under this head against 1,106,030 in 1900, the ratios being 23·46 and 23·58 respectively. Naini Tal (34·83), Bulandshahr (34·51), Budaun (34·41), Saharanpur (33·64), and Farrukhabad (33·52) were the districts which showed the highest fever death-rates. Even allowing for inaccuracies of the unskilled reporting agency, according to which nearly 80 per cent. of the total deaths in the province are set down to fever, the mortality from malarial disease, especially in rural districts, is still deplorable; in this connection it is satisfactory to note that nearly five times as many packets of quinine were sold in 1901 as in the previous year, the increased sales being almost entirely conducted by the post offices, and the price having been reduced.

Deaths from dysentery and diarrhœa fell from 30,652 in 1900 to 27,172, and the death-rate from ·65 to ·57. Garhwal, as usual, recorded the highest district death-rate, 7·06, and other high rates were 3·32 in Almora and 3·07 in Benares.

Plague, which in the previous year occasioned only 135 deaths, in 1901 established itself in the United Provinces. Altogether 10,190 cases and 9,778 deaths were reported, giving the heavy mortality of 95 per cent. The disease was practically confined to four districts, though sporadic cases occurred in seven others. In Ballia 5,278 deaths were recorded during the year, in Benares 3,064, in Jaunpur 712, and in Allahabad 661. Raniganj, the town in Ballia where the first outbreak occurred, is believed to have taken the disease from the infected district of Saran in Bengal, with which it has commercial relations. In order to combat the progress of the plague the Sanitary Commissioner observes that the policy has been adopted of enlisting the help of the affected community, of working with and not against the people, who as a rule show readiness in evacuating their houses and applying for disinfection.

Punjab.

There was considerable improvement in the health of the Punjab in the year under review; small-pox was less fatal, cholera was practically absent from the province, and there was a great diminution in the fever mortality. The vital statistics are based upon the census of 1901, which gives a total population for the province as at present constituted of 20,108,690. The total number of births registered was 712,533 against 843,970 in 1900, the corresponding ratios being 35·4 and 41 per 1,000. This decrease was largely due to the sickly autumn season of 1900. The provincial rate was made up of district rates ranging from 44·1 in Sialkot to 15·8 in Simla. As compared with the mean average for the previous five years the decrease in the birth-rate was most considerable in Ferozepore and Umballa, the deficit amounting to 16·7 and 14·9 per 1,000 respectively. The provincial birth-rate was lower than the death-rate by 0·7 per 1,000, and this excess of deaths over births was most marked in the Delhi Division, and in the districts of Ferozepore and Ludhiána.

From all causes 726,611 deaths were recorded, giving a death-rate of 36·1, against 980,211 or 47·69 in 1900. Thus, while the death-rate was exceeded only in Bombay Presidency, a fall of 10 per 1,000 from the figures of the preceding year was registered in the Punjab. Ludhiana (52·2), Karnal (51·5), and Ferozepore (48·8) were the unhealthiest districts in the province, while seven others exhibited high rates exceeding 40 per 1,000. In several cases, however, these rates, though high, were an improvement on the previous year's record, *e.g.*, in Hissar (43·7) the ratio was 52·0 less than in 1900. In the Multan and Rawalpindi divisions the mortality was lowest, the rates for the most part varying from 20 to 25 per 1,000. The death-rate was heavier among females than males, and infant mortality continued to rule high.

The province enjoyed almost complete immunity from cholera. Only 180 deaths, for the most part in the districts of Umballa and Karnal, were recorded from this disease, of which, in 1900, there were 28,260 fatal cases.

Small-pox was less prevalent, 6,154 deaths being returned under this head, giving a rate of 0·31, against 10,425 and a rate of 0·51 in the previous year. More than half the mortality occurred among children under ten years of age. The disease was most fatal in the districts of Montgomery and Jhang, where there were 1,082 and 1,298 deaths respectively, while in the district of Kangra only 20 deaths took place. This contrast

shows well the efficacy of vaccination, for in Kangra the number successfully vaccinated during 1900–1901 was 70 per 1,000, while in Jhang and Montgomery the ratios were only 26 and 20 per 1,000.

There was a marked diminution of fever mortality in 1901, the deaths being less numerous than in the previous year by 141,594. In spite of this the disease accounted for a death-rate of 25·3 per 1,000, and for 508,035 deaths or 70 per cent. of the total mortality of the year. The decrease took place in almost every district, and was most considerable in the three districts with the highest rates, viz., Hissar, Ferozepore, and Karnal, where the fever death-rate fell to 37·0, 39·9, and 39·6, against 70, 64, and 54 in 1900. The high mortality, especially in these districts, was largely due to the after-effects of the outbreak of the previous autumn. In Rohtak (37·4) and Ludhiana (34·4) the mortality was also in excess of the average of the province.

The mortality from dysentery and diarrhœa followed the fever mortality in its falling away from the dimensions of the previous year. 14,722 deaths were recorded giving a rate of 0·73. The decrease, amounting in all to 11,191 was general, and with few exceptions, was distributed throughout all the districts. The highest death-rates were reported from Simla (1·66), Umballa (1·51), Delhi (1·43), and Gurdaspur (1·32).

Plague effected a lodgment in the Punjab during the year under review, the mortality leaping from a total of 495 for 1900 to 14,959 at the lowest estimate for 1901. It appears, however, from returns compiled in the Plague Department that at least 17,000 deaths should have been recorded under this head. A marked increase took place in the three districts, Jullundur, Hoshiarpur, and Gurdaspur, which were plague-stricken in 1900, the number of deaths for the two years being 3,857 and 417, 2,308 and 43, 4,325 and 35, respectively. Seven fresh districts were infected, but of these only in Sialkot, adjoining Gurdaspur, was the mortality considerable; 3,695 cases terminating fatally. The disease was especially virulent towards the end of the year, 61 per cent. of the mortality being registered in November and December.

North-West Frontier Province.

The five districts comprising the North-West Frontier province usually enjoy good health, and the year 1901 was no exception. Harvests were generally good and the absence of famine, of plague, and to any considerable extent of cholera, kept the death-rate below the birth-rate by 10·3 per 1,000. There was a decrease in the number of births registered, viz., 60,413, against 62,084 in 1900, the rates being 29·5 and 30·3 respectively. This result must be set to the account of the unhealthiness of the previous year, and its influence upon fecundity. The decrease was most marked in the Pesháwar, Kohat, and Bannu districts.

A diminished mortality was also recorded in the year under review, 39,208 deaths or 19·2 per 1,000 being registered, against 52,103 or 30·0 in 1900. This rate was the smallest returned by any province of British India; it was composed of extremes varying from 25·6 in Dera Ismail Khan to 16·6 in Hazára. The mean death-rate in the 10 municipalities was 18·28.

Cholera only claimed 117 victims, against 3,275 in 1900, and was practically confined to the Pesháwar district. Treatment of the wells with permanganate of potash is reported to have been attended with excellent results.

There were 955 deaths from small-pox, 772 being children of 10 years or under. The death-rate from this cause was 0·47. The figures for the previous year were 1,390 and 0·68.

The fever mortality also diminished, although 74 per cent. of the total mortality was returned under this head. 29,108 deaths occurred, giving a rate of 14·23 against 17·35 in 1900.

From dysentery and diarrhœa 380 persons died, the resulting rate being 0·19. Of the total number of deaths 167 took place in Dera Ismail Khan district.

The province was free from plague throughout the year.

Central Provinces.

As compared with the previous year an improvement was manifested in the health of the Central Provinces, but 1900 was, with the exception of the famine year 1897, the worst on record as regards public health. The birth-rate still compares unfavourably with that of the other provinces and indicates a low vital condition of the people. The statistics of the year under review are based upon the census of 1901, which gave a total population of the British districts under registration of 8,673,030—the falling off during the last decade being accounted for by successive years of famine and plague, and by successive epidemics of cholera and small-pox.

A total of 279,998 births was registered, against 335,436 or 31·87 per 1,000 in 1900. The resulting birth-rate of 28·83 was the lowest recorded during the last two decades, save in 1897, when it sank to 26·83. In every district during 1901 it was below the decennial mean. The births exceeded the deaths in all districts but two, Bhandara and Chanda, where the birth-rates were remarkably low, viz., 21·35 and 20·60 respectively.

The deaths during the year numbered 227,853 or 23·46 per 1,000, against the terrible mortality of 1900, when 608,691 deaths occurred and the rate rose to 57·82. The provincial death-rate was exceeded in 11 districts, the mortality being highest in Jubbulpore (29·4), Wardha (29·3), Burhanpur (29·1), and Narsinghpur (28·9). Infantile mortality, calculated on the number of births during the year, was 246·41 for males and 224·63 for females.

The epidemic of cholera which raged in 1900 and carried off 75,112 people completely subsided. Only 49 deaths were returned under this head and the death-rate was infinitesimal (0·01).

The epidemic of small-pox continued from the previous year, but with less severity. 6,081 deaths were recorded against 8,021 in 1900, the corresponding ratios being 0·63 and 0·76. Of the victims, 4,591 were children under 10 years of age. Every district was affected, Nagpur with 1,851 deaths and a rate of 2·46, and Damoh with 682 deaths and a rate of 2·39 being the chief sufferers. Only one other district, Wardha (1·52), recorded a death-rate of over 1 per 1,000.

The bulk of the mortality was returned under the heading of fever. From this cause, 138,707 deaths were reported against 303,370 in 1900, the resulting death-rates being 14·28 and 28·82. The highest rate was recorded in Nimar, 23·9, and 12 districts in all exceeded the provincial rate. There was a slight increase in the number of packets of quinine sold, and towards the end of the year the price of the drug was reduced from 3 to 2 pies per five-grain powder.

A similar marked diminution of mortality from dysentery and diarrhœa was registered, the number of deaths falling from 58,474 to 11,487, and the death-rate from 5·55 to 1·18. Bhandara (0·14) again returned the lowest rate from this cause, and Wardha (2·77) the highest.

No cases of indigenous plague occurred in the year under review, and only 10 imported cases were noted. At the close of the year only two inspecting stations were being maintained, viz., Burhanpur and Wardha.

Burma.

There was some slight improvement in the checking of birth and death registers in Burma during the year. The total population of the province according to the census of 1901 was 9,252,175, but since registers of births are not kept in the rural districts of Upper Burma the available vital statistics are calculated on a registered population of 5,546,265. An increase of 1,085,238 has occurred since the census of 1891, on which the statistical data of previous reports have been based. This large difference vitiates any comparison of the figures of the year under review with those of the previous year.

The total number of births registered in Lower Burma rose from 171,183 in 1900 to 177,865. The birth-rate fell from 38·37 to 32·07. This anomaly is explained by the caveat entered above, since it is due to the new census enumeration being taken as the basis of calculation. Further, this rate (32·07), the Sanitary Commissioner remarks, "is scarcely consistent with the probabilities," falling short by over 6 per 1,000. Birth-rates recorded in districts ranged from 40·68 in Henzada to 12·70 in Rangoon. Of the towns the lowest rates were those of the seaports Rangoon 12·70, Akyab 18·61, Moulmein 21·13, owing to the disparity of the sexes and the large floating population. From the 13 towns under registration in Upper Burma a total of 11,334 births and a rate of 37·66 were returned. After allowance is made for the reduced census population of these towns, the figures indicate some improvement in registration.

The mortality in Lower Burma was slightly less: 120,565 deaths were registered against 122,714 in 1900. The calculated rates for the two years, 21·74 and 27·51, do not admit of comparison (as explained above). The incidence of mortality in urban and rural districts was 29·99 and 20·62 respectively. Four towns recorded rates of over 35 per 1,000 and five of under 21, the figures in the one case being attributable to epidemic diseases and in the other case to defective registration. The rate of infantile mortality returned for Lower Burma was 206·6 per 1,000 of male births and 168·6 per 1,000 of female births. In the towns of Upper Burma 10,010 deaths were recorded, giving a rate of 33·27. Mandalay returned the highest rate (35·80).

In Lower Burma the mortality from cholera increased slightly in the year under review: 3,552 deaths, or 0·64 per 1,000, occurred, against 3,440 in 1900. Prome (1·50), Thóngwa (1·28), Myaungmya (1·23), and Amherst (1·15) were the districts which chiefly suffered. Only one cholera death was reported from the towns of Upper Burma.

Small-pox accounted for 2,468 deaths in Lower Burma, against 3,014 in 1900. About 44 per cent. of the victims were children of 10 or under. This disease, like cholera, was practically non-existent in the towns of Upper Burma, only seven deaths being recorded under this head.

The fever mortality in Lower Burma was slightly less, 47,990 deaths being registered against 49,888. The resulting rate 8·65 is lower than that of any Indian province except Madras. The sale of quinine has fallen from 2,976 to 2,814 packets. In Upper Burma the mortality from fever increased very slightly, the figures for the year being 2,686 or 8·93. Among the districts of Lower Burma, Sandoway (14·86), Akyab (13·83), Mergui (12·50), returned the highest fever death-rates; Mandalay (10·82) and Kyauksè (10·15) exhibited the heaviest rates among the towns of Upper Burma.

Dysentery and diarrhœa caused 8,151 deaths and a rate of 1·47 in Lower Burma and 136 or ·45 in Upper Burma. The highest mortality was recorded in the towns of Allanmyo (4·81), Rangoon (4·55), Toungoo (4·17), Kyaukpyu (4·13), and Bassein (3·95).

The whole province enjoyed complete immunity from indigenous plague throughout the year, and only five imported cases were observed, three of which terminated fatally.

Assam.

The general health of the people of Assam was above the average of the provinces of British India during 1901. The statistical data for this review are based upon the census of 1901. Registration in Assam is not everywhere compulsory, and even where compulsory, is not always complete although checked by the police and the vaccination staff. For the general provincial ratios the figures for the Surma and Brahmaputra valleys are taken, viz., 5,275,706. The total number of births registered was 179,289 or 33·98 per 1,000, against 184,427 or 34·96 in 1900. The highest rate was again recorded by the Goalpara district 44·25, followed by Sylhet 36·49 and Cachar 35·38, these being the only three instances in which the provincial rate was exceeded.

There was a considerably diminished mortality during the year under review. In all 146,939 deaths occurred, against 161,631 in 1900, the corresponding ratios being 27·85 and 30·64 per 1,000. This indicates an improvement in the public health as compared not only with the two previous years but also with the average for the 15 years from 1884–1898, when the figures were 152,787 and 29·06 respectively. Darrang (35·19) and Goalpara (34·09) returned the highest death-rates among districts. The death-rates in the towns exhibited large variation, but save in the case of Sylhet (40·74) the importance of the high figures is minimised by the small numbers from which the ratios are calculated. The average of infant mortality for the province was 195·59 per 1,000 of registered births.

Cholera assumed much smaller proportions, only 7,468 deaths being recorded against 23,761 in 1900, the respective rates being 1·42 and 4·51. A succession of small epidemics in Kamrup and Cachar caused the highest death-rates of 2·88 and 2·84. Nowgong, which in 1900 suffered severely from the visitation of this disease, was almost completely free, the death-rate having fallen from 24·95 to 0·13. Among the coolies working in the tea-gardens the mortality from cholera was 2·17 per 1,000; only 58 out of 22,242 coolie immigrants died of the disease while being conveyed to their place of employment.

The incidence of small-pox was heavier than in the preceding year; 3,274 deaths occurred against 975 in 1900, giving rates of ·62 and ·18. Sylhet exhibited the heaviest mortality, 1·13 per 1,000, the several outbreaks in this district resulting in 2,540 deaths.

An increase in the number of deaths from fever brought the death-rate from this cause up to the level of the average for the 15 years from 1884–98, viz., 15·90. In all 83,696 deaths occurred, giving a rate of 15·86. Thus practically no improvement in this respect has taken place during the last two decades, and in the long run about 16 per 1,000 of the population each year die from the effects of malaria. The districts of Goalpara (29·70) and Darrang (23·89), as in the previous year, recorded the highest death-rates. The sale of quinine made but slow progress, and it is observed that "the drug has yet to gain the confidence of the people." Included in the total of 83,696 fever deaths are 5,856 deaths from kalá-ázár. This disease has been the scourge of the province for many years, as may be seen from the instances of Nowgong, Darrang and Kamrup. These three districts have specially suffered from the malady, and the

first and third have alone of the districts decreasing population during the last decade. It is satisfactory to note that the mortality from kalá-ázár has fallen 70 per cent. since 1897. The disease has been found to be more prevalent than was supposed in Sylhet, but as a set-off has practically disappeared from Goalpara, and the mortality during 1901 was heavy only in Darrang (2,446 deaths) and Nowgong (2,346 deaths).

From dysentery and diarrhœa 11,576 deaths were reported, against 14,996 in 1900, the provincial death-rates being 2·19 and 2·84 respectively. The rates in the various districts vary remarkably, ranging from 0·29 in Goalpara to 4·72 in Lakhimpur.

Madras.

In Madras the climatic conditions of the year were on the whole unfavourable to public health and the prices of food grains ruled high. The population of the Presidency, according to the census of 1901, was 38,623,666, showing an increase during the last decade of 2,572,646 ; but the population under registration during the year was 37,315,611. Registration in 1901 was compulsory in all municipal areas, and also, under the provisions of Madras Act III of 1899, in 441 villages against 400 in the previous year. The nominal birth-rate (25·1) and death-rate (21·3) for the province continue to be inaccurate. The Government of Madras observe: "There can be little doubt that the chief cause of the imperfection of the statistics is the failure to register the births and deaths of infants who die in the first few months of life."

There was a decrease of over 100,000 in the total number of births registered in 1901 as compared with the previous year, the figures being 935,749 and 1,049,199 for the two years respectively. This result is attributed partly to the influence of the high price of food upon fecundity, but mainly to the unfavourable character of the year 1900. The corresponding birth-rates are returned as 25·1 and 31·8 ; but the figure for the year under review is quite inaccurate, as the Government of Madras remark, "the actual birth-rate is certainly not less than 40 per 1,000," instead of 25·1. This is borne out by the returns from municipal towns where registration though defective is at least compulsory, the birth-rate for such areas being 32·6 per 1,000. Of districts, Madura (16·1), North Arcot (19·1), and Ganjam (20·5) recorded the lowest rates. The low rates of Madura and Ganjam, however, are to some extent fictitious, since, with regard to the large zemindari tracts in both districts, while the census population has been included in the calculations the actual births have not, statistics not being available. Among the other districts the most notable diminution of birth-rates occurred in Chingleput with a decrease of 13·6, North Arcot 9·8, Madras 9·0, Kistna 8·6, and Kurnool 7·5. In municipal areas the birth-rate, as stated above, was 32·6, which indicates, after allowance has been made for the more accurate registration in towns, that the pressure of high prices was chiefly felt in rural tracts.

The mortality in 1901 was higher than that of the previous year by 25,281, the total number of deaths registered being 796,140. The nominal death-rate was 21·3, which, the Government of Madras observe, "is nearly as inaccurate as the birth-rate." The returns for municipal towns showed a death-rate of 35·4 per 1,000. The highest rate was 55·5 recorded by Madras City. In the other districts the ratios ranged from 30·1 in Chingleput to 14·8 in Ganjam and 10·9 in Madura. Among municipalities the death-rate was considerably above normal in Bellary (48·1), Berhampur (40·5), and Chingleput (38·4). As regards infantile mortality, the provincial death-rate was returned as 166·2 per 1,000 of the registered births. This figure is far below the rates returned by the other provinces, and, when contrasted with the rates for municipalities, 237·3 per 1,000, and for Madras City, 295 per 1,000, is clearly defective. Of the rate in Madras City the Government state that "it does not err on the side of excess."

Of the chief diseases cholera accounted for a largely increased mortality, 81,370 persons having fallen victims to the disease as compared with 60,662 in 1900. The death-rate rose accordingly from 1·8 to 2·2, which is much higher than the figure for any other province. The districts which chiefly suffered were Salem (5·1), Anantapur (4·5), Cuddapah (4·2), and North Arcot (4·1). Among the towns with the greatest mortality from this cause were Madras 1,161 deaths or 2·4 per 1,000, Calicut 819 or 10·6, Salem 510 or 7·2, and Trichinopoly 306 or 2·9 ; but Vániyambádi with 333 fatal cases and Arcot with 160 returned the highest cholera death-rates, viz., 27·7 and 14·9.

Small-pox was somewhat less prevalent than in 1900, the total number of deaths registered under this head in the two years being 26,202 and 27,692 respectively, the resulting death-rates being 0·7 and 0·8. The rate of incidence in municipal towns where vaccination is compulsory was 0·6. Among districts the largest number of deaths occurred in Godavari (2·4) and North Arcot (1·1), and among municipalities in Cochin

(17·8), which lies adjacent to an area under native administration. Striking figures are given by the Sanitary Commissioner, which testify to the efficacy of vaccination in mitigating infant mortality from this disease. Contrasting the conditions at the beginning and at the end of the last decade, in 1891 and 1901 respectively, the infantile mortality from small-pox in rural districts has advanced from 7·3 to 8·6 per 1,000, while in municipal areas (where since 1894 compulsory vaccination has been universal) this same mortality has fallen from 8 to 2·7 per 1,000.

294,854 persons against 288,521 in 1900 were returned as having succumbed to fevers. These were chiefly malarial, though cases of typhoid occurred. The fever death-rate for the Presidency, 7·9, was composed of extremes varying from 18·3 in Madras to 3·6 in Anantapur. Kurnool, the Nilgiris, Nellore, Cuddapah, Vizagapatam, Kistna Ganjam, South Canara, and Godavari also recorded rates of 10 or over. For all these districts the mean fever death-rate of the previous five years was high.

From dysentery and diarrhœa there was an increased mortality, 42,084 deaths being registered against 38,858 in 1900. The rate of incidence for the Presidency was 1·1, whereas for municipal towns it amounted to 5·0. The force of the disease fell especially upon the following districts: Madras (9·7), Chingleput (3·5), South Canara (2·6), Malabar (2·3); towns: Palamcottah (15·5), Tuticorin (10·1), Madras (9·7), Chingleput (9·4).

Plague spread in the province during the year under review, 3,960 cases being reported against 895 in 1900. The total mortality was 3,035 or 76·6 per cent. of cases, giving a death-rate of 0·1. Of the municipalities, Vaniyambadi (769 cases) and Bellary (702) suffered severely. The chief source of infection was Mysore. Surveillance was kept up by the passport system with good results.

Bombay.

In the general health of the Bombay Presidency in 1901 some improvement was manifested on the terrible record of the previous year. The lasting effect of recent plague and famine was visible in the low birth-rate, and in the whole Presidency 220,487 more deaths than births were registered in the year under review. The statistics of the present review are based upon the census of 1901, which gives a total population, exclusive of Europeans and Eurasians, of 18,481,362. In comparing the birth and death rates for 1901 and 1900 there is an even larger decrease than appears from the figures given below, since the ratios for the latter year (1900) are based upon the larger census population of 1891.

The birth-rate in 1901 (25·19) was the lowest recorded during the last decade. In all 465,647 births were registered, against 505,662 in 1900. The lowness of the rate is ascribed to weakness induced by famine; this condition began to take effect upon the birth-rate in April, 1900, reached its climax in March, 1901, and passed off in December, 1901, when the rate again reached the mean of the previous ten years. The district birth-rates ranged from 33·43 in Khandesh to 8·36 in Thar and Parkar, in which district it was probably due to the exodus caused by scarcity. The number of births recorded was less than in the previous year in all but six collectorates. For the most part the birth-rates were higher among the rural than the urban population, especially in the Poona collectorate, where the figures were 29·63 rural and 11·70 urban.

A decrease of nearly one-half in the number of deaths in the Presidency brought down the death-rate from 70·07 in 1900 to 37·12. In all 686,134 deaths were registered, against 1,318,783 in the previous year. Of the five Registration Districts, the Southern, which suffered from plague, cholera, and famine, returned the highest death-rate of 56·77 per 1,000. In the collectorates the rates ranged from 77·78 in the City of Bombay to 13·21 in the Upper Sind Frontier. Belgaum (71·91), Dharwar (71·26), Ahmedabad (52·68), Broach (50·38), Kaira (48·36), and Sátara (43·35) also returned high rates, all having suffered at some period of the year from plague or famine.

Cholera was only severe in Dharwar (6·87), Belgaum (2·87), Bijapur (1·95), and Kanara (1·44), these being the only districts with a rate of above 1 per 1,000. In all there were 13,600 deaths from this cause, contrasted with 163,889 in 1900, the provincial rates being respectively 0·74 and 8·71. Some 60 per cent. of the attacks proved fatal.

A diminished mortality from small-pox was also recorded, the figures for 1901 and 1900 being 5,340 or 0·29 and 9,885 or 0·52. Only two collectorates were free from the disease which was most prevalent in the Southern Registration District; 68·5 per cent. of the victims were children of 10 years of age or under.

Under "fever" 291,951 deaths were registered, against 543,319 in the previous year, the resulting death-rates being 15·80 and 28·87. In the collectorates of Ahmedabad

(43·69), Broach (27·81), Kaira (25·19), Panch Mahals (21·50), and Thar and Parkar (22·25) high rates were recorded, famine being adduced as the predisposing cause.

The number of deaths ascribed to dysentery and diarrhœa fell from 218,243 or 11·59 per 1,000 to 60,198 or 3·26. This decrease was spread over all the collectorates except Dharwar and Kanara. The highest ratio was recorded in Sholapur 8·12, followed by Ahmednagar and Belgaum with 6·68 and 6·24. Since the famine year of 1897 the number of deaths from this cause has increased greatly, but for the year under review the number fell just within the decennial average.

The plague mortality in 1901 was the highest recorded since the first appearance of the disease in 1896, 128,259 deaths having occurred, giving a rate of 6·94, against 33,196 or 1·76 in 1900. The areas chiefly affected were Belgaum with a rate of 34·07, Dharwar 28·65, Sátára 19·26, and the City of Bombay 24·58. The epidemic spread to 1,582 towns and villages, whereas it was confined to 587 in the previous year Of the deaths, 33,803 occurred in Belgaum, 31,877 in Dhárwár, 22,075 in Sátára, and 18,694 in the City of Bombay. No other collectorate returned more than 4,258 (in Poona).

Berar.

The year was an extremely healthy one in the Hyderabad Assigned Districts. The low birth and death rates are believed to be the result of the recent famine. The vital statistics are based upon the census of 1901, which returned a population of 2,717,346. Inspection of registration though less in amount was more effective in 1901, since there was an increase of 2·2 in the percentage of omissions discovered.

The low birth-rate of 30·8 was recorded for the year under review, being the result of 83,762 births, against 89,302 or 31·3 in 1900. This result is attributed to the condition obtaining in 1900, when famine prevailed and few marriages took place. In July, 1901, nine months after the cessation of famine, the birth-rate began to rise, and for the whole year compared favourably with the recorded rates of the Central Provinces, Bombay, and Madras.

The abnormally low death-rate of 27·6 is ascribed to two causes. The province was free from epidemic diseases and many of the aged and weakly had succumbed to privation in the previous year. As was stated in last year's review, 130,599 or more than half of the persons who died during 1900 were either children under five or old people over 60 years of age. The Sanitary Commissioner remarks that to compare in detail the statistics of the exceptionally healthy year under review with the enormous rates, under every head, which characterised the year 1900 would serve no useful purpose.

The province was practically free from cholera, only 17 fatal cases being reported, of which 16 occurred in Akola. The wells were freely treated with permanganate of potash.

Small-pox claimed 190 victims, chiefly from the districts of Wun and Amraoti ; 108 of these were children under 10 years of age.

The mortality from fevers and from dysentery and diarrhœa was greatly reduced. The former caused 37,848 deaths, against 84,017 in 1900, the latter 11,853, against 63,860, the respective death-rates being 13·9 from fevers and 4·4 from dysentery and diarrhœa. Akola, Amraoti, and Wun were the chief sufferers from the former, while all the districts except Wun and Buldana recorded rates above the provincial average from the latter.

Plague was absent throughout the year.

IV.—JAILS.

Sickness and mortality in 1901.

The health of the jail population of India during 1901 was good as compared with the previous year. Fewer admissions into hospital, less overcrowding, and a marked diminution of the death-rate were the features of a year in which "normal conditions were restored in the provinces which had suffered from scarcity in 1900." Sickness, however, was very prevalent, and although the percentage of fatal cases was smaller, the average both of admissions into hospital and of daily sick showed an increase over the two years immediately preceding.

Thus the daily average sick per 1,000 of average strength rose from 32·4 in 1900 to 34·3, the ratio of admissions into hospital from 851 to 882, while the death-rate declined from 33·4 to 25·3. Save in the United Provinces, Punjab, Assam and Coorg, the death-rate everywhere decreased, and notably in Berar, the Central Provinces, Bombay, Bengal and Burma; in Burma it was the lowest on record; for the rest, which in 1900 were the chief sufferers from the ravages of cholera, their improved condition is largely due to the subsidence of this disease. The total number of cholera deaths fell to 106 giving a death-rate of less than 1 per 1,000 of average strength. Omitting Coorg, which has only one jail, the most unhealthy administrations were, in spite of the improvement on the previous year's record, Bombay and Bengal. The most prevalent diseases were ague, dysentery and influenza; the most fatal dysentery, tubercle of the lungs and pneumonia.

The following statement shows the sickness and mortality among all classes of prisoners in the jails and subsidiary jails of the various provinces for 1901, as compared with the previous year:—

Provinces.	1900. Ratio per 1,000 of Average Strength.			1901. Ratio per 1,000 of Average Strength.		
	Admissions.	Daily Sick.	Deaths.	Admissions.	Daily Sick.	Deaths.
Bengal	1,173	39	40·3	1,096	38	27·6
United Provinces of Agra and Oudh.	764	36	22·1	840	40	24·2
Punjab	1,239	38	23·6	1,253	38	26·9
Burma	555	28	21·2	547	26	15·2
Central Provinces	934	30	69·0	867	28	27·5
Assam	817	35	22·8	1,029	42	24·5
Coorg	628	24	54·6	654	35	165·9
Madras	412	23	25·4	476	24	21·7
Bombay	778	25	56·8	964	34	35·0
Berar	943	27	79·9	676	21	24·9
India	851	32	33·4	882	34	25·3

Bengal.

The health statistics of the Bengal jails are satisfactory, and do not call for the unfavourable comment which was passed last year. Although the figures are still high, some improvement is manifested under every head. The admissions into hospital were in the ratio of 1,096 per 1,000 of average strength, as against 1,173 in 1900; the average daily sick-rate fell from 39 to 38, and the death-rate from 40·3 to 27·5. This death-rate is considerably below the decennial average (32·7), and is also below the rate (31) for the general population. Among all classes of prisoners there were 588 deaths,

and of these 533 were convicts. The mortality in the jails is seen to be largely dependent on the poor condition of the prisoners when first admitted, for while among prisoners who had been less than six months in prison the death-rate was 39 per 1,000, it was only 21·7 per 1,000 among those between six months and a year in jail. Cholera sensibly abated, only 17 cases terminating fatally as against 78 in the previous year, and the number of deaths from specified diseases is less in every case than in 1900. The most fatal diseases were dysentery (153) deaths, tubercle of the lungs 78, pneumonia 57. Out of 48 jails there were seven in which the death-rate exceeded 40 per 1,000, the highest being Hooghly 81·4, Barisal 78·9, and Bankipore 74·5. In the last of these (as in others of the seven with excessive mortality) there were severe epidemics of plague and cholera. In two jails there were no deaths, and among the jails returned with the lowest mortality it is satisfactory to find Suri, Bogra, Daltonganj and Faridpur, all of which had shown a very high rate for several years previously.

United Provinces of Agra and Oudh.

The sanitary history of the jails in the United Provinces of Agra and Oudh is marked by a slight change for the worse. The ratio of admissions to hospital has risen from 764 per 1,000 of average strength in 1900 to 840; the average of daily sick from 36 to 40, and the death-rate from 22·1 to 24·2. Increased mortality was recorded from tubercle of the lungs, dysentery and heatstroke, and was also heightened by epidemics of cerebro-spinal fever and cholera. The death-rate, however, compares very favourably with that of the free population (30·30). Of the 55 jails in the province there were no deaths in two, and 36 others kept below the provincial average. The jails with the highest mortality ratios were the district jails of Allahabad (58·5), Moradabad (56), Banda (54), and Lucknow Central Jail (44·9); in the first of these three several outbreaks of cerebro-spinal fever sent up the death-rate from 29·9 to 58·5; in the last there was a severe epidemic of cholera causing 27 deaths, and as an indirect consequence a virulent type of dysentery (24 deaths) owing to prisoners having to be in cholera camp during the rains. This was part of a general epidemic affecting alike Lucknow City, cantonments and the surrounding villages. The notoriously unhealthy jails at Mirzapur and Azamgar recorded the low death-rates of 9·7 and 17·2 respectively. As in the previous year Bara Banki, with a single death from an average daily strength of 414, has a good record, closely followed by Partabgarh with one death from an average strength of 323. Beyond the 32 fatal cases of cholera, dysentery caused 163 deaths against 132 in 1900, tubercle of the lungs 106 against 84, pneumonia 67 against 102. Of the 712 prisoners who died 682 were convicts, their death-rate being 24·7 against 22 in 1900.

Punjab.

The standard of health among the prison population in the Punjab was lower than in 1900. While the average of daily sick remained stationary, the ratio of admissions into hospital per 1,000 of average strength rose from 1,239 to 1,253 and the death-rate from 23·6 to 26·9. The pressure on accommodation continued to be considerable. No cases of cholera or small-pox occurred during the year, and the mortality ratios from tubercle of the lungs, pneumonia and dysentery, though still remaining high, displayed some improvement. Out of 28 jails five reported no deaths, while 12 exceeded the ratio of 30 per 1,000. Of these, however, all but four were small jails (for the most part situated in districts where there was high mortality among the general population), in which the high ratios were largely due to the bad state of the prisoners when first admitted. A similar reason is adduced for the increased mortality at Ferozepur (54·26), Delhi (37), and Umballa (36·34); at Mung Rasul (37·21) an epidemic of cerebro-spinal fever broke out in spite of the good sanitary condition of the jail, baffling all measures of prevention and resulting in 29 deaths. Of specified diseases malarial fever, dysentery and diarrhœa were the most prevalent, pneumonia (with 4·9 deaths per 1,000 of average strength), and dysentery (with 4·8 deaths per 1,000) the most fatal. Nearly one-third of the total 362 deaths resulted from diseases of the lungs in some form, and all but 17 of the victims were convicts.

Burma.

The standard of health among prisoners was higher in Burma than in any other administration. The ratio of admissions into hospital per 1,000 of average strength still further diminished from 555 in 1900 to 547, the average of daily sick from 28 to 26, and the death-rate from 21·2 to 15·2, which is the lowest on record. The accommodation in some few cases was temporarily overstrained, but the pressure was promptly relieved by transfers elsewhere. Of the 181 deaths that occurred during the year all but seven were convicts. In five jails and in the European side of Rangoon jail no deaths occurred.

Paungde (63·49) and Bhamo (51·95) exhibit the highest mortality, but they are small jails, and in the first-named there were four deaths from cholera. This disease was also epidemic at Insein, the second largest jail, where it resulted in 20 cases and 12 deaths. Of diseases malarial fevers and bowel complaints were the most prevalent, tubercle of the lungs with 47 deaths, dysentery with 27 deaths, and cholera with 16 deaths the most fatal. Moulmein maintains its reputation for unhealthiness, the number of admissions to hospital for dysentery and diarrhœa alone being 428 out of a total for the whole province of 1,207.

Central Provinces.

The vital statistics of the jails in the Central Provinces betoken a decided improvement in the health of the prisoners and more especially in the mortality ratios. While the rates of admission to hospital and the average of daily sick per 1,000 have fallen from 934 and 30 in 1900 to 867 and 28 respectively, the death-rate has dropped from 69 to 27·5. This is the more satisfactory because the admissions, the Inspector General states, "included a large proportion of persons broken in health and habits by the recent famine." There was but little overcrowding, and relief was found in utilizing worksheds as sleeping-places. In 3 of the 19 jails there were no deaths; of the 6 jails noted as exceptions to the low death-rate generally prevailing, Bhandara with 67·58, Mandla with 60, Jubbulpore with 49·68 stand highest, but in no case did the actual number of deaths exceed six save at Jubbulpore (54), Nagpur (14), and Raipur (15). Of the 132 fatal cases all but six were convicts. No deaths occurred from small-pox, remittent fever, or cholera, but in the matter of bowel complaints the prisoners compare unfavourably with the free population of the Central Provinces. Cerebro-spinal fever, which in 1900 produced 22 cases, all but one of which terminated fatally, was confined to two jails in the year under review.

Assam.

The health of the prisoners in Assam was on the whole good. The ratio of admissions into hospital per 1,000 of average strength rose from 817 in 1900 to 1,029, the average of daily sick from 35 to 42, and the death-rate from 22·8 to 24·5. There was rather more sickness than in the previous year but really less mortality resulting therefrom, since the enhanced death-rate was the result of 4 deaths not due to disease. The marked improvement in the health of the prisoners consequent upon the partial discontinuance of extra-mural work in 1900 is thus maintained. In only three of the 24 jails was the average strength over 100, viz., Sylhet, Tezpur, and Gauhati, and these three contributed 32 out of the 40 deaths, their rates being 32·98, 31·48, and 29·99 respectively. In 16 jails no deaths took place.

Madras.

Madras was one of the healthiest provinces, being surpassed only by Burma. The ratio per 1,000 of admissions into hospital rose indeed from 412 to 476, and the average of daily sick from 23 to 24, but the death-rate fell from 25·4 to 21·7. This in view of the congestion of the prison population, the continuance of scarcity and the consequent impoverished condition of many admitted to jail is satisfactory. Cholera continued prevalent both in an epidemic and sporadic form; the disease made its appearance in three central and five district jails, resulting in 34 deaths. 21 of these occurred at Madura District Jail where the epidemic was specially virulent. In every case complete or partial evacuation was resorted to and attended with the best results. Of prisons which exceeded the provincial death-rate, the case of Madura (84·61) has already been noted; Trichinopoly Central Jail returned 30 cases and 6 deaths from tubercle of the lungs and 40 cases with 16 deaths from tubercle of the intestines, but this place was virtually a convalescent depôt, owing to the accumulation there of old and decrepit prisoners; Vellore (27·74) was visited by cholera. At Rajahmundry the number of admissions to hospital (chiefly from dysentery and malarial fever) was largely in excess of the provincial rate. At Nellore, which last year recorded the high death-rate of 51·5, only one death occurred on an average daily strength of 229. 283 prisoners in all died, and of these 261 were convicts, of whom 100 had been in jail for less than six months. Among diseases cholera and tubercle of the lungs proved more fatal, and dysentery and diarrhœa less fatal, than in 1900.

Bombay.

The vital statistics of the jails in the Bombay Presidency indicate an increase of sickness but a reduced mortality. The ratio per 1,000 of admissions into hospital was 964 as against 778, the average of daily sick 34 as against 25, while the death-rate was 35 as against 56·8 in the previous year. Overcrowding occurred in every jail but three; on the other hand improved dietary and other hygienic measurse were undertaken during

the year. Six jails recorded a ratio of mortality in excess of the provincial average, viz., Sind Gang 121·0, Rajkot 74·1, Bombay House of Correction 71·1, Bombay Common Jail 57·2, Ahmedabad 43·8 and Thana 39·3. The high rate in the Sind Gang was due to pneumonia, 49 out of 53 deaths being attributable to that cause. At the Bombay House of Correction there were 17 deaths from plague. Famine was, perhaps, the predisposing cause of mortality in the two Gujarati jails, Rajkot and Ahmedabad, in the latter of which more than half the number of deaths (61) occurred among prisoners within six months of admission. The mortality at the special prison at Thana was greatest among natives of the Deccan. In all there were 419 deaths, of which 367 were of convicts. Pneumonia (103 deaths) and tubercle of the lungs (37 deaths) showed increased mortality, the death-rate of the former being higher in Bombay than in any other administration. There was no cholera, but plague appeared in five jails. No deaths were reported from Aden.

Berar.

The health of the prisoners in Berar during 1901 has followed the improvement manifested in the condition of the general population and may be described as normal. Owing to the lull after the famine there was less pressure upon accommodation. The abnormally high death-rate of 79·9 per 1,000 of the previous year sank to 24·9, the ratio of admissions to hospital from 943 to 676, and the average of daily sick from 27 to 21. There were 35 deaths in all which occurred chiefly in the central jails ; 18 at Akola, and 9 at Amraoti ; in the former 16 deaths took place in the first half-year—a fact which points to the lingering of the unfavourable conditions prevalent in 1900,—in the latter there was an epidemic of influenza. Yeotmal district jail and Amraoti central jail also exhibited the highest ratios for admission to hospital. Sickness (in the Assigned Districts) was chiefly due to malarial fever, and mortality to respiratory diseases (15 deaths). Two deaths were reported from Secunderabad, and sickness was rather more prevalent than in the previous year, but the health of the prisoners was on the whole good.

V.—VACCINATION.

General results.

During 1901-02 there were 8,036,444 persons vaccinated in the several provinces of India, being an increase of 162,052 on the number of the previous year. The increase was spread over six provinces, chief among them being Bengal and Madras. In the five provinces showing a decrease Bombay came first with a falling off of nearly 140,000, followed by Burma with a decrease of nearly 60,000, the Punjab with 40,000, and the Central Provinces with 30,000. Plague and the effects of famine caused the decline in Bombay and the Punjab, and the effects of famine affected work in the Central Provinces. According to age, 3,167,075 children under one year of age, and 3,209,462 children between the ages of one and six years were successfully vaccinated during the year. The proportion of population protected against small-pox by the year's operations ranged from 49·2 in Coorg to 20·5 in Ajmer-Merwara. In the vaccination of infants the best results were obtained in Berar, the Punjab, the United Provinces, and the Central Provinces, and the worst in Burma and Coorg.

Statement showing the total number of persons successfully vaccinated during the year 1901–02 :—

Province.	Population among whom Vaccination was carried on (Census of 1891).	Number of Persons vaccinated.	Ratio of successful Vaccinations per 1,000 of Population.	Number of Children successfully vaccinated.		Percentage of Children born during the Year (calculated at 40 per 1,000 of Population) successfully vaccinated.
				Under One Year of Age.	Between One and Six Years of Age.	
Bengal	74,801,731	2,662,826	34·34	775,729	1,482,590	25·93

Ajmer-Merwara	476,912	10,841	28·55	8,032	2,421	42·11
TOTAL	236,992,296	8,036,444	31·36	3,167,075	3,209,462	33·41

Bengal.

The total number of vaccinations performed in Bengal during 1901–1902 was 2,662,826 of which 2,568,798 were successful, against corresponding figures in 1900–1901 of 2,346,311 and 2,248,015. This shows an increase of 316,515 vaccinations in 1901–1902, which was spread over almost all the districts of the province, the increase being most striking in Mymensingh (43,215), Midnapore (35,927) 24-Parganas (33,177), Backergunge (25,766) and Faridpur (23,720). In the first three of these districts the increase was chiefly occasioned by the severe epidemic of small-pox with which they were visited. Only four districts reported a decrease, the most marked case being Dacca where the vaccinations were fewer by 11,934. The primary operations numbered 2,529,778, of which 95·04 per cent. were successful. According to age,

775,729 of the successful primary vaccinations were of children under one year of age, and 1,482,590 were between one and six years. For the whole province the successful vaccinations were in the proportion of 34·34 per 1,000 of the population. Estimating the births during the year at 40 per 1,000, the percentage of infants successfully vaccinated was 25·9.

Three methods of vaccination are practised in the province—(1) with lymph taken direct from the calf, from which 323,884 operations were performed; (2) with lanoline lymph, 244,244 operations; (3) with human lymph taken by arm to arm transfer, 1,961,650 operations. Compared with the previous year's figures there was an increase of 43,352 in the number of primary operations performed direct from the calf.

As regards the attitude of the people towards vaccination the Sanitary Commissioner reports that "there is scarcely any district in Bengal where there is not some opposition in some form or other. Infant vaccination is very unpopular in most parts of the province. Parents hide their children from the vaccinators in the belief that the operation would cause them pain and lead to suffering and disease. In fact deaths from other causes months after children are vaccinated are attributed to vaccination."

United Provinces of Agra and Oudh.

Steady progress continues to be made in vaccination work in the United Provinces of Agra and Oudh in spite of the presence of plague. "In the nature of things," the Sanitary Commissioner remarks, "vaccination must always be carried out among the most uneducated classes, and among people suspicious to a degree. The work of vaccination has been slowly built up step by step, year by year, and it says much for the confidence placed in officials, that even during a period when plague has attacked the provinces, no great falling off or opposition to vaccination has been observed, and that even a gratifying increase in work can be shown." During the year under notice 1,580,195 persons were vaccinated, being an increase of 30,962 on the number in 1900–1901. The increase was shared in by 31 out of the 48 districts, and in several instances the increases were over 1,000, the highest being 3,373 in Allahabad. The primary vaccinations numbered 1,490,966, of which 97·71 per cent. were successful. The number of persons successfully vaccinated per 1,000 of population was 31·37, against 31·11 in the previous year. Estimating the birth-rate at 40 per 1,000, 45·54 per cent. of children born during the year were successfully vaccinated. Bovine lymph is only used to a very small extent in the province, the total number of primary operations performed with pure calf lymph being only 18,132, of which 97·34 were successful.

Punjab.

Excluding the figures for the frontier districts, transferred to the new province, the aggregate number of vaccinations in the Punjab in 1901-02 was 668,144, as compared with 713,951 in the preceding year. The falling off is accounted for by a decrease in the number of births, scarcity, malarial fever, a general unhealthiness which rendered children unfit for vaccination, and other causes. The primary vaccinations numbered 511,121, with a percentage of success of 93·92. The decrease is most notable in the Gurdaspur, Umballa, Lahore, and Ludhiana districts, where the decrease in primary cases varied in round numbers from 9,000 to 5,000. The number of successful cases among children under one year of age fell from 462,392 or 55·7 per cent. of the births, calculated at 40 per 1,000 of population, to 377,482 or 46·5 per cent. The provincial ratio of persons successfully vaccinated per 1,000 of the total population was 28·2, against 33·3 in the previous year. The highest proportion of persons successfully vaccinated per 1,000 of population was as usual in Kangra district. It is reported that the good work there has practically stamped out small-pox. The Vaccination Act was not extended to any additional town during the year.

North-West Frontier Province.

In the North-West Frontier Province the aggregate number of vaccinations performed in 1901–1902 was less by 7,486, as compared with the previous year. Out of the total of 70,993 vaccinations, 63,321 were primary cases, and of these 91·03 were successful. The falling off was entirely in primary vaccination, as the number of re-vaccinations rose from 4,865 to 7,672. Of the successful primary cases more than two-thirds were vaccinated from animal lymph, while only 1,738 cases were from human lymph. The prejudice against vaccination is reported to be disappearing, and the practice of inoculation to have almost ceased. "One inoculator," it is stated, "is working in Boner, and the Bonerwalas bring their children into British territory to be vaccinated."

Burma. The total number of persons vaccinated in Burma during the year 1901–02 was 360,224, as compared with 410,461 in the previous year, showing a decrease of 50,237 operations. Out of 333,657 primary cases, 90·1 per cent. were successful, against 91·7 in the previous year. The number of infants protected was 80,448, equal to 19·9 per cent. of the estimated number of births. The returns for the Rangoon municipality still continue to be unsatisfactory. Calf lymph is used generally throughout the province, arm-to-arm vaccination being resorted to when the supply of animal vaccine fails. Inoculation is said to be freely carried on throughout the province, and Civil Surgeons generally, the Sanitary Commissioner states, report that it is favoured and supported by the majority of Burmans.

Central Provinces. In the Central Provinces 425,392 persons were vaccinated during the year, showing a decrease of 30,005 on the number of the previous year. The falling off was entirely under primary vaccinations, and was due to a low birth-rate, the poor health of the people, and the closing of the famine camps. Primary vaccinations fell from 385,493 to 350,484, and the percentage of success was 96·80 against 96·57 in 1900. The ratio of successful vaccinations in the year to the total population was 33·80 per 1,000, as compared with 33·42 in 1900–01. In the protection of infants there was a falling off of 7,528, the number vaccinated under one year of age during the year having fallen from 218,824 to 211,296. Animal lymph was used in the bulk of the vaccinations, and worked very successfully. Arm-to-arm vaccination is practised in very few places. With the lymph obtained from calves 208,613 children were vaccinated during the year, and of these 95·63 per cent. were successful. The use of glycerinated calf lymph was attended with satisfactory results, the percentage of success attained being 90·96 against 86·97 in the previous year.

Assam. During the year 1901–02 280,827 vaccinations were performed by all agencies in the province of Assam, showing an increase of 9,361 on the previous year's work. Of the total operations 271,600 were primary cases, and of these 97·48 per cent. were reported as successful, against 95·99 in the previous year. The province contains only 13 circles, municipalities, unions, cantonments, &c., where vaccination is compulsory under the Act, and in these nearly 80 per cent. of the available children under one year of age were vaccinated against 70 per cent. in the previous year. In the town of Nowgong no less than 94 per cent. of the available children were protected. The number of infants successfully vaccinated in the province was 64,747, representing only 26·4 per cent. of the births estimated at 40 per 1,000 of the population, and the proportion of the population successfully vaccinated in the year was 44·5 per 1,000. The Vaccination depôt at Shillong continued to work successfully, and 395,317 tubes were loaded with calf lymph against 387,557 in the previous year.

Madras. The total number of vaccinations performed in the Madras Presidency during 1901–02 was 1,325,106, being an increase of 67,223 on the operations of the previous year. The increase was partly due to the extension of vaccination to Local Fund areas and partly to the fact that the people are abandoning the idea that vaccination is a means of infecting them with plague which operated detrimentally to vaccination in the two previous years. Of the total, 1,235,196 were primary cases, of which nearly 90 per cent. were successful. The number of children under one year of age successfully vaccinated rose from 350,763 to 356,467, which represented only 23·3 per cent. of the estimated births. Vaccination is compulsory in all municipalities, and the number of operations performed by municipal vaccinators rose from 131,195 to 146,010. In the town of Madras the number of operations performed was 38,265, an increase of 5,694 on the previous year. Of the 21 districts, nine recorded a decrease of work. Chief among the causes assigned for the decline is incompleteness of staff and insufficiency and inertness of lymph. Nearly all the operations were performed with animal lymph, and the best results were obtained, as usual, from calf-to-arm vaccination, with a percentage of success of 98·4.

Bombay. There was again a considerable decrease in the number vaccinated in the Bombay Presidency in 1901–02. The number of operations fell from 661,001 operations in 1900–01 to 521,706. The decrease occurred in all the districts and is attributed to a low birth-rate consequent upon the incidence of famine and plague. The total primary cases fell from 586,478 to 470,517, the percentages of success being respectively 90·86 and 91·9. Animal and human lymph were used in the Presidency during the year. In the

use of the former the ratios of success in the registration districts ranged from 89·8 to 70·9 per cent., and in the latter from 93·4 to 86·8 per cent. In the City of Bombay vaccination with animal lymph has been in use for many years past. Of the successful primary cases 74 per cent. were infants under one year of age. Reckoning the births in the Presidency at 40 per 1,000 of population, 37·5 per cent. were protected from small-pox. No inoculation was reported to have been practised anywhere during the year, and no instances were reported of any disease having been communicated through vaccination. The protection afforded to the population by the year's operations was in the ratio of 21·5 per 1,000.

Berar.

Vaccination work in Berar regained some of the ground lost in the previous year, owing to famine conditions and epidemic disease, the number of persons vaccinated having risen from 107,788 in the previous year to 120,418, or an increase of 12,630. The primary vaccinations rose from 74,707 to 82,296; and in each year the proportion of success was 96·6. Estimating the births at 40 per 1,000 of population, 53·9 per cent. were protected against small-pox, and the proportion of population protected by vaccination rose from 27·3 per 1,000 in the previous year to 29·9. Lanolinated lymph manufactured at Amraoti was used exclusively, and was found as efficacious as the pure calf lymph and more economical. The Sanitary Commissioner gives some striking figures showing the efficacy of vaccination in checking small-pox mortality in Berar; the ratio of successful vaccinations per 1,000 of population has risen from 8·92, the mean of five years 1868–69 to 1872–73, to 33·6, the mean of five years ending 1897–98; the mortality from small-pox for the same periods has declined from 2·02 to 0·19 per 1,000. In the four years 1898–99 to 1901–02 the ratios of successful vaccinations per 1,000 of population were 34·6, 43·2, 27·3, and 29·9, and the death-rate from small-pox 0·2, 0·1, 0·3, and 0·07 per 1,000. The Vaccination Act is in force in all the municipal towns.

VI.—MEDICAL INSTITUTIONS.

Civil Hospitals and Dispensaries.

The following comparative statement shows the number of hospitals and dispensaries under official control open in the several provinces of India during 1901 and the previous year, and the number of patients under treatment :—

Provinces, &c.		Number of Institutions.	Number of In-door Patients.	Number of Out-door Patients.	Total Number of Patients.
Bengal	1901	550	49,362	3,662,477	3,711,839
	1900	532	50,097	3,417,284	3,467,381
Calcutta and Howrah	1901	17	25,989	253,615	279,604
	1900	17	28,372	251,822	280,194
United Provinces of Agra and Oudh	1901	364	55,328	3,661,957	3,717,285
	1900	365	55,394	3,577,776	3,633,170
Punjab	1901	245	51,565	2,973,446	3,025,011
	1900	273	59,328	3,379,034	3,438,362
North-West Frontier Province ...	1901	29	6,750	449,874	456,624
Burma	1901	119	39,027	858,200	897,227

	1900	47	6,051	297,939	303,990
TOTAL	1901	2,323	362,373	20,597,137	20,959,510
	1900	2,294	372,022	19,924,225	20,296,247

Bengal.

The total number of dispensaries at work during 1901 in Bengal, exclusive of the medical institutions at Calcutta, was 550, an increase of 18 on the number of the preceding year. At these there were 3,711,839 patients under treatment, 49,362 being in-door and 3,662,477 out-door patients, against 50,097 and 3,417,284 respectively in the previous year. This shows a total increase of 244,458. The slight falling off in in-patients was attributed to the comparative healthiness of the year, and the rise in out-door attendance to the greater popularity of the dispensaries. There was again a satisfactory increase in the number both of women and children patients. The increase among women amounted to 47,529, the number having risen from 539,563 to 587,092. The proportion of women to the total daily attendance rose from 17·55 in the previous year to 18·29. Of the diseases under treatment at the dispensaries, malarial fevers, skin diseases, and dysentery and diarrhœa were responsible, as usual, for the largest number of cases. Of malarial fever there were 653,997 cases, equal to nearly 18 per cent. of the total number of patients, against 629,746 in 1900 ; of skin diseases the number of cases rose from 591,500 to 681,687 ; of dysentery and diarrhœa there were 177,314 cases, against 185,507 in 1900. The number of cholera

cases fell from 21,371 to 8,143. Cases of venereal diseases rose from 82,131 to 85,808. The number of deaths among in-door patients fell from 6,430 or 128·3 per 1,000 of total treated in 1900 to 5,266 or 106·7 in 1901. During the year 1,889 plague cases were treated in the dispensaries against 656 during 1900. A disease locally known as "Bhatput," which was ascertained to be prevalent in a portion of the Khondmals of the Orissa Tributary States during the rainy season of 1900 was, under the orders of the Government, investigated and pronounced to be one of virulent syphilis, "spreading rapidly in a tribe," it is stated, "which was probably uninfected until recent years, and aggravated by a low state of health brought about by famine conditions." A dispensary for the efficient treatment of the disease has since been opened. Great attention is paid in these institutions to surgery, and during the year 157,377 operations were performed, of which 230 terminated fatally. Among the more important operations there were 2,482 cases of extraction of the lens.

The following statement shows the number of in-door and out-door patients treated in the several hospitals and dispensaries in Calcutta and Howrah during 1901 and the previous year :—

Name of Institution.	1900.				1901.			
	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.

The figures for 1900 show a decrease of 2,383 in in-door patients, and an increase of 1,793 in out-door patients. The increase in the latter, however, "was chiefly in-patients suffering from minor diseases, but is evidence of the growing popularity of the out-door departments of the hospitals, especially of the Medical College Hospital." The death-rate for all the hospitals was 153·1 per 1,000 of the total in-patients, against 172·5 in the previous year. Cholera patients fell from 728 to 442, and the fatal cases from 445 to 227. The decrease was most marked in the Campbell Hospital, where 154 cases were treated against 271 in the previous year. Small-pox was more prevalent in Calcutta than in the previous year, and the cases admitted to hospital rose from 253 to 463. The disease, however, was chiefly confined to Campbell Hospital which contributed 443 cases. Dysentery patients fell from 9,171 to 7,211. The number of patients treated for diarrhœa also fell from 8,949 to 7,231 ; malarial fever was responsible for 48,817 patients against 54,571. Plague cases treated rose from 449 to 458, and the deaths from 357 to 361. Venereal diseases show a small decrease of 232 patients, the number treated having fallen from 12,328 in the previous year to 12,096. Surgical operations increased from 26,023 to 27,552, and death ensued in 207 cases, against 188 in 1900.

United Provinces of Agra and Oudh.

During 1901 there were 364 hospitals and dispensaries at work in the United Provinces of Agra and Oudh, or 1 less than in the previous year. The number of patients who received medical aid was 3,717,285 against 3,633,170 in 1900. There was thus an increase in 1901 of 84,115. The number of in-patients fell from 55,394 to 55,328. In the previous year the decrease in attendance was due in a great measure to plague scares and plague preventive measures, which still deterred patients from seeking medical relief at Government charitable dispensaries ; but the returns for the year under notice indicate that many of the institutions which suffered most in this respect were again becoming popular, and that the confidence of the people in them was being re-established. Among the in-door patients there were 2,950 deaths, against 3,099, and the death-rate fell from 55·9 to 53·3 per 1,000. Of the diseases for which the patients were treated 523,227 were suffering from malarial fevers, a decrease of 54,819 on the number of 1900 ; 2,449 cases of cholera were treated in the dispensaries, against 4,679, and cases of diseases of the eye rose from 337,464 to 345,320 From venereal diseases there were 78,052 patients, against 82,884 in the previous year. The number of surgical cases rose from 182,986 to 186,561, of which 158,260 resulted in cure and 360 were fatal. Of the total operations 5,844 were for cataract, of which nearly 85 per cent. were successful, as compared with 5,373 operations and a percentage of success of 83 in 1900.

Punjab.

The number of dispensaries at work in the Punjab during 1901 was 245 or 28 less than in the previous year, the decline being due to the transference of 28 of the dispensaries reported on in 1900 to the North-West Frontier Province, consequently there was a decline in the number of patients. During the year 3,025,011 patients were under treatment, being a decrease of 413,351 on the number of 1900. The attendance of in-door patients was less than in the previous year by 7,763, the number having fallen from 59,328 to 51,565. Of the diseases for which patients sought relief there were only 121 cases of cholera, a large decrease on 4,663 in 1900. Fever cases were by far the most frequently treated, the cases of malarial fever amounting to 550,719, or 18 per cent. of the total patients. Diseases of the eye showed a decrease of 60,863 cases, the number treated in 1901 being 381,863 against 442,699. From venereal diseases there were 28,378 cases under treatment. Among the in-patients there were 2,344 deaths during the year, being in the ratio of 45·4 per 1,000 of the number treated, against a death-rate of 68·7 in 1900. The number of surgical operations amounted to 151,837, which, compared with the previous year, shows a decrease of 13,395 operations. Of the total operations, 144,995 resulted in cure and 253 were fatal. There were 6,387 cataract operations, and of these 5,204 were successful.

North-West Frontier Province.

In the North-West Frontier Province 29 dispensaries were at work during 1901, and at these the total number of patients was 456,624. Of the 6,750 in-patients 5,099 were cured, 904 relieved, 399 discharged otherwise, and 243 died. The chief maladies from which the patients sought relief were malarial fevers, diseases of the eye, ulcers and diseases of the digestive system. There were only 24 cases of cholera. The total number of operations performed was 19,650, of which 19,405 were cured, and 45 were fatal.

Burma.

The number of dispensaries existing in Burma at the end of 1901 was 119, or six more than in the previous year. At these, 897,227 patients attended, as compared with 858,689 in 1900. The number of in-door patients rose from 36,095 to 39,027, of whom 29,522 were cured, and 2,854 or 73 per 1,000 died, against 2,724 deaths or 75 per 1,000 in the previous year. About 57 per cent. of the patients treated were Burmese. Malarial fevers, as usual, headed the list of maladies under treatment, the number of cases being 145,655, against 136,619 in the previous year. Cholera was slightly more prevalent than in 1900, and the number of cases rose from 220 to 250. Cases of venereal disease rose from 29,692 in 1900 to 29,931. Surgical work showed an increase of 988 operations, the number performed during the year having risen from 19,061 to 20,049. The number of patients cured, after being subject to operation, was 19,147 and 124 died.

The figures for the Dufferin Hospital show that the total number of patients during 1901 was 1,865, of whom 253 were in-door, against 1,223 and 512 respectively in 1901. This hospital provides accommodation for maternity and for gynecological cases, besides quarters for 24 pupil midwives, who undergo a course of instruction in

midwifery and sick-nursing. Since the opening of the hospital in 1888 up to 1900, 154 nurses had passed out, and of these 14 were in the employment of municipalities.

Central Provinces.

The number of hospitals and dispensaries at work in the Central Provinces during 1901 was 103, the same as in the previous year. The total number of patients rose from 1,343,986 to 1,347,932. The increase, however, extended only to out-door patients, the in-door patients having fallen from 13,725 to 10,592. The decrease in in-patients was chiefly due to the healthiness of the year, and the consequent diminution in the number of famine waifs. Among the in-patients there were 977 deaths, or 92·2 per 1,000 of total treated, against 2,083 or 151·2 in 1900. As regards the different kinds of diseases, malarial fevers headed the list with 328,964 cases. Of cholera there were only 7 cases, against 6,566 in the previous year, and of dysentery and diarrhœa, 41,937 cases against 79,103, and of venereal diseases 29,034 cases. The number of surgical operations rose from 32,472 in 1900 to 32,809. Of these, 31,793 resulted in cure and 60 in death. Of the more important operations, 904 were for extraction of the lens.

Assam.

In the province of Assam there were 131 dispensaries at work during the year, or 3 more than in the previous year. There was a further increase in the number of patients, the total under treatment having risen from 702,590 in 1900 to 734,682 in 1901. These institutions, it is stated, are steadily becoming more useful and better appreciated by the people. The number of in-patients again rose from 6,369 to 6,539, and of these 3,994 were discharged cured, 656 relieved, 806 discharged otherwise, and 792 died, the latter representing 121·1 per 1,000 of the total in-patients, against a ratio of 140·1 in 1900. The attendance of women largely increased as compared with previous years, and is attributed to the improved accommodation offered to female patients by the introduction of separate consulting rooms. Of the total number of persons who received medical aid, malarial fever accounted for 168,370 cases, including 2,592 suffering from kala-azar, against 2,013 of these cases in the previous year; dysentery and diarrhœa 31,024, and venereal diseases 8,230. Cholera patients fell from 2,717 in 1900 to 1,052. Of surgical cases there were 15,689, of which 15,144 were cured and 27 were fatal.

Madras.

In the Presidency of Madras there were 479 civil hospitals and dispensaries working at the close of 1901, or one more than in 1900, and at these there were 4,751,692 patients under treatment, exceeding the number of the previous year by 65,939. Of the 64,714 in-door patients, 37,697 were returned as having been cured under treatment, 11,716 as relieved, and 6,934 as otherwise discharged. The deaths numbered 5,938, representing a ratio of 91·8 per 1,000 of the total in-patients. Ulcers and diseases of the skin, malarial fevers, diseases of the digestive system, rheumatic affections, and diseases of the eye were the most common complaints under treatment during the year. Cholera was more prevalent in the Presidency than in the previous year, and the cases under treatment in the various hospitals and dispensaries rose from 10,336 to 10,833. Of venereal diseases there were 93,984 cases. The surgical operations fell from 153,633 in 1900 to 151,695. Of these, 142,461 were cured and 295 were fatal.

At the Madras Voluntary Venereal Hospital, which is included in the above hospitals there were 611 female patients treated during 1901, an increase of 86 on the number of the previous year. Of these, 289 were cured and 12 died.

Bombay.

In the Presidency of Bombay, there were 238 hospitals and dispensaries working at the end of 1901. At these, 1,603,794 patients were under treatment, of whom 45,191 were in-door and 1,558,603 out-door patients, against 50,888 and 1,485,534 respectively in 1900. Malarial fevers, as usual, constituted by far the largest number of cases (417,524), and showed an increase of 54,854 on the figures of the previous year. Next to fever, eye and skin diseases and worms were the most common ailments. Cholera cases fell from 12,047 to 430; dysentery cases were also far less numerous; and patients suffering from venereal affections rose from 33,897 in 1900 to 38,258 in 1901. The number of persons admitted into hospitals for plague was 104, of whom 24 died. Of the in-door patients 30,712 were cured, 4,829 relieved, 3,003 discharged otherwise, and 4,528 died, the ratio of deaths to total treated being 106 per 1,000, against a ratio of 134 in the preceding year. The total number of patients operated on was 63,948, as compared with 62,965 in 1900, and of the former 49,251 were cured and 346 died.

Berar. There were 48 medical institutions at work in Berar during 1901, or one more than in the previous year. Of these, eight are hospitals wholly maintained by the State. The total number of patients under treatment was 390,021, against 303,990 in 1900. In-patients numbered 5,943, and of these 4,805 were cured and 435 died, which gives a death-rate of 73·0 per 1,000. The increase was entirely among out-door patients, and was accounted for by the closing of permanent dispensaries during the late famine and the opening of temporary hospitals at relief works and poor-houses throughout the province. Malarial fevers continued to head the list of diseases from which relief was sought; nearly a fourth of the total patients were treated under this head; diseases of the eye and diseases of the digestive system came next in order. The number of surgical operations rose from 9,882 in 1900 to 12,277. Of these, 12,087 were cured and 40 were fatal.

At the Lady Dufferin Hospital for women and children at Amraoti the number of in-door patients fell from 230 in 1900 to 139, and the out-door patients from 6,839 to 5,334. The number of operations performed fell from 139 to 99.

Lunatic Asylums.

Bengal. At the six asylums in Bengal (viz., Bhowanipore, Dullunda, Dacca, Patna, Cuttack, and Berhampore) 1,192 lunatics, including 249 fresh admissions and re-admissions, were under treatment in 1901, being an inecrease of 8 on the number of the previous year. In the course of the year under notice 95 patients were discharged as cured, and 27 as improved or otherwise, and 61 died. Compared with the figures of 1900, the number discharged was less by 11, and the mortality more by 39. At the end of the year there were 1,009 persons still under detention, or 66 more than at the close of 1900. The lunatics are reported to have enjoyed excellent health during the year The number of admissions to hospital fell from 968 to 576; the average daily number of sick fell from 80 to 77; while the death-rate fell from 106·7 to 61·8 per 1,000 of average strength. There was only one solitary case of cholera against 12 in 1900. Although plague raged in the neighbourhood of the Patna Asylum only one fatal case occurred in it. The patient was segregated, and happily no other case occurred. The cause of insanity was traceable only in 49·4 per cent. of the 249 fresh admissions, and 47 of these were ascribed to ganja smoking. The results of the working of dairy farms at the asylums were not so satisfactory as in the previous year. The dairy farms at Dullunda, Dacca and Berhampore showed a total profit of £63. The usefulness of the dairy farms, however, is not indicated so much in the profits as in the supply of pure milk and in the congenial work which they afford to the lunatics.

In the Bhowanipur Asylum, containing European and Eurasian patients, included in the above total, the inmates during 1901 numbered 48, or five less than in the previous year. Of this number 37 were under detention at the beginning of the year, and 11 were subsequently admitted. In the course of the year 12 patients were discharged, 4 died, leaving 32 under confinement at the close of the year. As regards the health of the patients during the year, there were only 5 admissions to hospital, against 6 in the previous year.

United Provinces of Agra and Oudh. The inmates of the four lunatic asylums (Agra, Bareilly, Benares, and Lucknow) in the United Provinces of Agra and Oudh in 1901 numbered 1,362, including 250 fresh admissions during the year, against 1,358 in 1900. Before the close of the year 189 patients were discharged, of whom 132 were reported as cured and 96 died, leaving 1,077 under treatment at the end of the year. The cause of insanity was unknown in nearly half (654) the cases under treatment.

Punjab. The new Central Lunatic Asylum for the province of the Punjab was opened on the 1st March, 1900, and within that month the patients from the old asylums at Lahore and Delhi were transferred to it, and the two institutions were permanently closed. The total number of lunatics in the Punjab lunatic asylum during 1901 was 610, including 128 fresh admissions, against 605 in 1900. At the end of the year the number was reduced to 479 by the discharge of 75 patients, and 56 deaths. As regards the health of the inmates of the asylum, the daily average sick was 54, a somewhat higher rate than 42 of the previous year, while the death-rate fell from 114·0 per 1,000 of average strength to 79·4.

The Rangoon Asylum is the only one in the province of Burma, and has accommodation for 416 insanes. The maximum number confined in any one night was 425. During 1901 there were 522 patients in the asylum, including 132 fresh admissions, and the total was reduced at the close of the year to 421 by the discharge of 65 patients for different causes and the death of 36. As regards the general health of the inmates, the daily sick rose from 17·1 to 29·3, and the deaths from 23 or 60·9 per 1,000 of average strength to 36 or 88·0. **Burma.**

In the two asylums of the Central Provinces (Nagpur and Jubbulpore) there were 354 lunatics under treatment during 1901, a decrease of 39 on the number in 1900. In the course of the year 33 patients were discharged as cured or otherwise and 20 died, leaving 301 still under treatment at the end of the year. The health of the inmates was better than in the previous year. The daily average sick at Nagpur fell from 10 to 9, and at Jubbulpore it was about the same (3). "Many of the inmates of the former asylum," the Medical Officer states, "are mere wrecks of men and women; an unhealthy season tells heavily upon them." Of the total 20 deaths, Nagpur recorded 10, being in the ratio of 67·6 per 1,000 of average strength, against 19 or 115·2 in 1900. At Jubbulpore there were 10 deaths, being in the ratio of 63·3 per 1,000, against 4 or 24·8 in 1900. Of the 301 patients under treatment at the end of the year the cause of insanity was unknown in 224 cases. **Central Provinces.**

There is only one lunatic asylum in the province of Assam, and this is situated in Tezpur. The total number of lunatics under treatment in the asylum during 1901 was 148, or two less than in the previous year. Of these, 34 were fresh admissions. At the close of the year the patients in the asylum were reduced to 130, 13 of the total number having been discharged, and 5 having died. The daily average sick was 8, and the number of deaths was less by 12 than in 1900, and the death-rate fell from 138·6 per 1,000 of average strength to 41·9. The causes of insanity were unknown in 19 of the fresh admissions. **Assam.**

At the commencement of 1901 there were 559 patients under treatment in the three lunatic asylums (Madras, Vizagapatam, and Calicut) of the Madras Presidency. During the year 155 fresh cases were admitted, bringing the total population up to 714, or one less than the number in the preceding year. In the course of 1901 there were 93 cases of discharge, and of these 66 were cured or improved. The accommodation was ample, and there was no overcrowding in any of the asylums during the year. On the whole there was less sickness among the patients than in the previous year. The daily average sick fell from 74 to 61, but the deaths rose from 49, or 89·8 per 1,000 of average daily strength, to 53 or 94·2. The excess mortality is more than accounted for by cholera, from which there were 4 deaths in Madras Asylum and 3 in the Calicut Asylum. Of the total 53 deaths the Madras Asylum contributed 35, giving a death-rate of 87·4 per 1,000 on an average strength of 400, against a ratio of 104·2 in 1900. The death-rates of the other two asylums, Vizagapatam and Calicut, were 55·5 and 154·6 per 1,000 respectively, against 57·0 and 49·0 in the previous year. Of the 155 fresh cases in the Madras Asylums 16 were under 20 years of age and 104 were between the ages of 20 to 40. The causes of insanity were unknown in 90 or 58·0 per cent. of the new admissions. **Madras.**

The total population of the six lunatic asylums of the Bombay Presidency (Colaba, Ratnagiri, Poona, Dharwar, Ahmedabad, and Sir Cowasji Jehangir, Hyderabad) was 1,069, including 310 fresh admissions, against 1,089 in 1900. In the course of the year 219 patients were discharged, 69 of them as cured, and 77 died, leaving 773 under treatment at the close of the year. There was slightly less sickness in the asylums than in 1900, the daily average sick having fallen from 42 to 41, and the death-rate from 178·0 per 1,000 of average strength to 100·0. The highest death-rate was recorded at the Ahmedabad Asylum, viz., 108 per 1,000 of average strength. Of the total of 1,069 lunatics, the causes of insanity were unknown in 450 cases. **Bombay.**

Medical Schools.

The number of medical schools open in Bengal during 1901–02 was 10, or one more than in the previous year. The Medical College, Calcutta, and four of the medical schools are maintained by Government, the rest are unaided. The college is affiliated to the **Bengal.**

University, and prepares candidates for its various medical degrees. The four Government medical schools train pupils as Civil Hospital Assistants, and the five unaided schools follow their own standards for private practice.

The students of the Medical College are required to undergo three University examinations during their five years' study, viz., the Preliminary Scientific examination at the end of the second year, the first L.M.S. or the first M.B. examination at the end of the third year, and the second L.M.S. or second M.B. examination at the end of the fifth year. The total strength of the College at the end of the session 1901–02 was 599 (including 13 women), against 569 in the preceding year. As regards the examinations, 267 candidates were successful, or at the rate of 44·57 per cent., as compared with 42·29 per cent. in the previous year. Of the 267 successful candidates, 32 passed the Preliminary Scientific L.M.S. examination, 51 passed the first, and 64 the second L.M.S. examinations; 89 passed the Preliminary Scientific M.B. examination; nine passed the first and two the second M.B. examinations. In the combined Preliminary Scientific and First L.M.S. examinations ten passed; and the same number passed the combined Preliminary Scientific and First M.B. examinations.

Sixty-two certificates were issued to pupil nurses and 45 for native *dais*.

The average number of students attending the four Government Vernacular Medical Schools at Calcutta, Patna, Dacca and Cuttack was 694 (including 45 women). 112 pupils passed the final examination. One female pupil was successful from each of the Temple and the Orissa Medical Schools, while 50 per cent. of the female candidates passed from the Campbell Medical School, Calcutta.

United Provinces of Agra and Oudh.

The number of pupils attending the Agra Medical School in 1901–02 was 242 (including 52 women), or 10 more than in the preceding year. The results of the examinations are reported to have been satisfactory, especially in the case of the female students. The pupils are carefully examined at the end of each year's work, and are not promoted to the next higher class unless they pass the annual examination of their class.

Punjab.

The average attendance at the Lahore Medical College and School was more by 29 as compared with that of 1900–01, viz., 472 against 443. Of these 181 were in the College and 291 in the Medical School. "The success of the graduates," the Local Government remark, "who pass out of the College in their subsequent careers is very gratifying. A considerable number have proceeded to England and obtained qualification there, and many fill with distinction appointments both in the Punjab as well as other provinces in India." The results of the year's examinations show that for the Preliminary Scientific Examination 29 out of 47 candidates passed. In the first L.M.S. and M.B. examinations 12 candidates out of 19 passed, against 23 out of 45 in the previous year, and in the second L.M.S. and M.B. examinations eight out of 30 passed, against 21 out of 43; in all 49 out of 96 or 51 per cent. were successful, as compared with 58 out of 111 or 52 per cent. in the previous year. In the final examination for the hospital assistant diploma 28 passed out of 64, which is considerably below the average.

The Medical School for Christian women continues to make progress and to do good work at Ludhiana. The object of the institution is "to provide a thorough medical training, under fully qualified Christian women, for those Christian women and girls who wish to prepare themselves for medical mission work." At the end of 1901 there were 44 students on the rolls, or one more than in the previous year; of these 14 belonged to the Medical class, three to the Compounders' classes, 11 to the Midwifery class, and 16 to the Nurses' classes.

Madras.

The number of students at the Madras Medical College (including the School Department) during 1901–02 was 524, of whom 26 were women students. In the Hospital Assistant Department, consisting of 209 pupils, 55 appeared for the final examination and 48 passed. The results of the several University examinations in medicine were again unsatisfactory, only 40 having passed out of 81 candidates entered, against 31 out of 68 in 1900. Of the 524 students 489 completed their curricula, 209 of them studied in the Hospital Assistant Department, 135 in the College Department, 103 in the Apothecary Department, and only one in the Chemist and Druggist Department.

The only other medical school at work during the year was the Prince of Wales' Medical School, Tanjore. At this there were 19 pupils on the rolls, all of whom

were being prepared for the Hospital Assistants' Certificate. Nine candidates appeared for the final examination and 5 passed.

Bombay.

The attendance at the Grant Medical College, Bombay, rose from 439 in 1900–01 to 569 (including 45 women) in 1901–02. For the first University examination in medicine 157 candidates presented themselves, of whom 104 passed; and for the second examination in medicine 90 passed out of 169 candidates. For the final examination for the degree of L.M.S there were 62 candidates, and of these only 28 passed.

The Government Medical Schools at Poona, Ahmedabad, and Hyderabad continued to work satisfactorily. The average number of students on the rolls was 235 (including five women).

VII.—SANITATION.

Bengal.

In Calcutta the improvement of bustees, or clusters of native huts, continued; work was in progress or in contemplation in more than 100 bustees. Some progress was also made in the extension of the filtered and unfiltered water supply, and a scheme was worked out for the prevention of waste and for a continuous supply. The average daily consumption of filtered water was 20,433,227 gallons, equal to over 24 gallons per head of the population. The Health Officer reports that the quality of the filtered water compares very favourably with that of the largest towns in Europe. The total length of filtered water mains and services amounted to nearly 317 miles on the 31st March, 1902. Arrangements were being made to extend the unfiltered supply to all the sewered roads throughout the city, thus directly relieving the demand for filtered water. The total mileage of unfiltered water pipes was 158 miles. The reconstructions connected with the Suburban Drainage Scheme progressed but slowly, pending a reference to Mr. Latham, the English expert, but greater expedition is anticipated in carrying out the scheme as approved by Government. Four lakhs of rupees were expended during the year on the town and suburban sewage outfall and the works connected therewith, the most important work in hand being the completion of the main sewer from Kidderpore to Ballygunge and of the outfall. A surface drainage scheme for the suburbs was in preparation.

The municipalities of the interior of Bengal spent £146,912 or nearly 45 per cent of their income on sanitary works (original and recurring) during the financial year 1900-01, being an increase of £6,426 on the expenditure of the previous year. This was distributed over all the important heads of sanitation, especially drainage and conservancy. The expenditure on conservancy has increased since 1895 by over £20,000. Various sanitary works were also undertaken or completed in towns and rural areas, by municipalities, district boards, Government, and private individuals, at a total cost of over £68,000.

The Sanitary Board held only one meeting during the year, but continued to advise the Government and local bodies on the important sanitary projects of the year. Among these were schemes for the improvement of the water supply of Howrah, the Garden Reach Municipality, a complete project for the surface drainage of Manicktollah, and drainage schemes, of varying magnitude, for the municipalities of Dinajpur, Monghyr, and Titaghar. Among the more important preliminary estimates prepared under the order of the Board were those for the Narayangunge waterworks, the Rangpur drainage scheme, the Patna Distillery water-supply improvement, and a combined scheme for water supply to the riparian municipalities.

United Provinces of Agra and Oudh.

No details regarding municipal or district board income or of the expenditure on sanitation in the United Provinces of Agra and Oudh appear in the report. In the towns of Agra, Allahabad, Benares, Cawnpore, Lucknow, Meerut, Mussoorie, Dehra Dun, and Naini Tal, containing about one-third of the municipal population of the province, the great water-supply works continued to work well. At Agrà the quality of the water supplied greatly improved, in Benares extensive sewerage works were in progress, while at Lucknow and Cawnpore important sewerage and drainage schemes were under consideration. Village sanitary inspection books are now kept up in almost all districts and are inspected by district officers on tour; by this means, it is anticipated, "much can be done to improve the general health of those living in rural areas."

The Sanitary Board met five times in the course of the year, when projects and estimates amounting to £48,300 were considered. The Board noted with satisfaction the continued attention which was paid to improving the sources of water supply and to the general improvement manifested in the sanitary condition of villages to which the Village Sanitation Act III of 1892 has been applied.

Punjab.

In the Punjab the municipal towns spent over £81,000 on sanitary works during 1901. The record of sanitary progress for the year was satisfactory. Among the more important schemes completed, were the extension of the Delhi waterworks and the drainage of Abbotabad and Fázilka. At Simla progress was made in the

extension both of the water-supply and of the sewerage system, 14 out of 18 miles of main being laid for the latter purpose during the year; an experimental installation was also set up for the biological treatment of sewage. There were under consideration projects for the drainage of the Simla bazaars and of the towns of Rawalpindi, Multan, and Ferozepore. Several schemes were being recast owing to financial difficulties. The estimate for the Amritsar waterworks, amounting to over £83,000, was sanctioned by the Government of India early in the year. The sale of manure by the municipal towns of the province brought in £10,000 to municipal funds. As regards rural sanitation there remains room for great improvement, though the system of village sanitation note-books was maintained and extended and the work of clearing and repairing wells continued.

The Sanitary Board held five meetings during the year, at which schemes were approved for the drainage of Chunian, Umballa (extra-mural), Chiniot Road Town, Gujrat, and Lyallpur, and for the water-supply of the latter place. Rules for the distribution of executive work between the sanitary engineer and the Sanitary Board were drawn up and submitted to Government, and a standing sub-committee was constituted for the preliminary discussion of projects submitted for approval.

North-West Frontier Province.

The municipal towns of the North-west Frontier Province spent over £7,000 out of their total income of £43,234 on sanitation. No large works for improving water-supply were undertaken during the year, but projects were under consideration for extension of the present supply at Kohat and Abbotabad. Drainage schemes were in progress at Peshawar, Kohat, and Bannu, and under consideration for Dera Ismail Khan. The sale of manure and street sweepings brought in £1,150. The work of repairing and cleaning wells continued, especially in the Dera Ismail Khan District. Sanitary note-books were distributed as usual.

Central Provinces.

Of the sanitary works undertaken by the Public Works Department of the Central Provinces, the increase in the storage capacity of the Ambajheri reservoir at Nagpur was the most important. This work, begun during the famine, was pushed forward practically to completion; further additions were also made to the Wardha waterworks. The chief municipal improvements effected during the year were the construction of drains at Nagpur and Jubbulpore, the cost being partly borne by municipal funds and partly recovered from the persons chiefly benefited. Of the total income of district headquarters municipalities for the year 1900–01, some $33\frac{1}{3}$ per cent. was spent on sanitary works, original and recurring. "The expenditure" under this head, it is observed, "whether under the direction of the Sanitary Board or otherwise, was very small." Owing to the recent famine neither funds from the District Councils nor subscriptions from private persons were readily forthcoming. The work of sanitary improvement was thus considerably restricted, and in some places brought to a standstill. The machinery of the Sanitary Board was made more workable by the abolition of the Central meetings and the substitution of District consultations. Four such consultations took place during the year in the Jubbulpore, Narsinghpur, Hoshangabad, and Nimar districts. The provisions of the Village Sanitation Act were extended to two fresh villages during the year under review.

Burma.

Although the income of the 42 municipalities in Burma was considerably higher than in the preceding year (£440,000 against £310,000), a much smaller proportion was spent on sanitary works; only 35 per cent. was assigned for this purpose, or 20 per cent. less than in 1900. The decrease was spread over all the main heads of sanitary expenditure—conservancy, water-supply, and drainage. Towards the end of the year work was commenced on projects for the water-supply of Moulmein and Rangoon, estimated to cost £62,000 and £26,000 respectively. Schemes for the water-supply of Meiktila, Akyab, Myingyan, and Minbu, and smaller schemes for other towns, were further considered during the year. On rural sanitation a sum of £10,000 was expended during the year from district cess funds. A number of municipalities had important schemes on hand which they are unable to carry out for want of funds; the question of rendering assistance from provincial revenues was receiving the consideration of the Local Government.

Assam.

No sanitary work of capital importance was undertaken during the year in Assam, nor was there any large provincial scheme under consideration. The municipalities,

however, excluding four towns which have no separate income of their own, spent £8,200 or over 55 per cent. of their income on sanitation; of this total conservancy absorbed considerably more than half. The municipality of Dhubri spent nearly 90 per cent. of its income on sanitation, Gauhati and Tezpur and the Habiganj union followed with upwards of 65 per cent., and the other bodies with two exceptions, spent upwards of one-third. The sanitary expenditure of the various local boards was almost entirely confined to effecting improvements in the water-supply by the construction of wells and the excavation of tanks. The system of sanitary inspection books was kept up in certain villages, but owing to lack of interest in sanitary matters was productive of few good results. The Sanitary Board held only one formal meeting during the year, the papers being circulated to members as occasion arose.

Madras.

In Madras City a sum of £16,300 was expended on new works during the year. The bulk of the amount was incurred on the new drainage scheme. The quantity of water supplied from the Red Hills Lake was about 10 per cent. greater than in the previous year; but the level of the lake was lower at the close of the year than at the beginning, and pumping had to be taken in hand from the commencement of April to the middle of October.

Details are lacking as to the proportion of sanitary expenditure to income among the municipalities and district boards in the Madras Presidency. The construction of the waterworks extension and protective works at Trichinopoly which were commenced in 1900 were still in progress—the extension to Worriur one of the suburbs being the only work of capital importance completed during the year. Some progress was also made in connection with the Vizagapatam and Coconada waterworks, and the scheme for the water supply of Ootacamund from the Tiger Hill reservoir. District medical and sanitary officers inspected and reported on 424 towns and villages; the action taken as a result of their reports has effected valuable improvements in respect of village water-supply, conservancy, and the sanitation of schools. Sanitary inspection books were satisfactorily maintained during the year. Progress in sewage farming, sewage filtration, and the employment of town sweepings and nightsoil for agricultural purposes continues to be made. The Government accorded sanction to a series of experiments on the use of sewage filtrates as fertilisers.

The Sanitary Board scrutinised the plans and estimates of 85 sanitary works, of which 38 were for municipalities, 43 for local fund boards, three for the collector of Madura and one for the collector of Salem. The total estimated cost of these projects was £96,000. Schemes for the water supply of Erode, Kumbakonam, and Ongole were among the more important of those examined and submitted to Government. Proposals for many other schemes were considered by the Board but were not sufficiently advanced for estimates to be prepared.

Bombay.

In Bombay City good progress was made with the various drainage works, but the proposed works for the drainage of the lower parts of the city, which had received the sanction of the Corporation, had not been taken in hand. Drainage connections were carried out for 4,132 houses at a total cost of £6,800, and a sum of £7,207 was expended on miscellaneous drainage. The various municipal waterworks were maintained in a state of efficiency. During the year 158 water connections were made, bringing the total up to 20,552. The Tansa and Tulsi Lakes were well replenished by the rainfall. In view of continued complaints about the bad quality of the Tulsi water a pipe scraper was passed through the main, the result being not only an improvement in the quality of the water but an increase in quantity.

The other 165 municipalities in Bombay Presidency spent rather less than 20 per cent. of their income, or £95,000, on sanitary works. The expenditure of the local boards on water supply and drainage was only 4·24 per cent. of income. The continued presence of plague necessitated considerable expenditure, while the prevalence of famine reduced the funds available, and thus few sanitary projects of great importance were undertaken during the year. The same causes prevented any progress being made in extending the Bombay Village Sanitation Act, 1889, to fresh villages. Sanitary inspection books were in use in 3,395 selected villages.

The Sanitary Board considered and tendered advice concerning several projects, among which the more important were the following:—Schemes for the water-supply of Kaira and Mehmedabad; plans and estimates for the water-supply of Ahmednagar, which were approved by Government; and a modified scheme for the drainage of Poona, the com-

plete project for drainage and water-supply submitted in the previous year having been vetoed by the Government of India on account of the excessive cost. Considerable progress was made in connection with the Poona sewage farm at Manjri ; 15 acres of land had been acquired and fenced in and experiments were in progress.

The municipalities of Berar spent 36 per cent. of their income on sanitation as compared with 45 per cent. in 1900. A similar decrease took place in the sanitary expenditure of district boards, especially those of Akola and Amraoti, under the heading of water-supply. Little progress was made in the sanitary survey, 111 villages only being surveyed ; 37 towns and 1,373 villages have been, two towns and 3,870 villages have still to be, surveyed. The District Sanitary Board met as usual once at each of the six headquarter stations to consider the action taken on the suggestions of the Sanitary Commissioner, as recorded in his remarks on towns and villages surveyed in past years. Berar.

OF

SANITARY AND OTHER REPORTS

FOR

1901.

15131

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER WITH THE GOVERNMENT OF INDIA, FOR 1901.

(*Surgeon-General Sir B. Franklin, K.C.I.E., I.M.S.*)

Meteorology of the Year.

Summary of the meteorological conditions of the year.—The following report on the meteorology of India has been kindly furnished by the Meteorological Department of the Government of India :—

A series of depressions entered North-West India and advanced eastward across Northern India during the month of January, and temperature changes were consequently frequent during that month. The warm and cool waves usually preceding and following depressions of the winter type were, however, less well-marked than is the case when the depressions are separated by longer intervals of time. The mean maximum temperature of the whole month was in moderate to large defect over the whole of Northern India and the north of the Peninsula, but the variations from the normal were more irregular and less strongly marked in minimum temperature. Both maximum and minimum temperatures were in slight to large excess over the southern half of the Peninsula. The conditions in February closely resembled those of January. The temperature changes were again frequent, due to the same cause. The mean minimum temperature of the month was again in moderate to large excess over the southern half of the Peninsula, but the excess in maximum temperature shown over the same area in January had disappeared and the mean maximum temperature of the month was normal in that region, while it was in slight to considerable defect in the north of the Peninsula and the whole of Northern India, except Assam and parts of Bengal. The minimum temperature of the month was in moderate to considerable defect in the West Punjab, Sind and Gujarat, in moderate excess in North-East India and in moderate to large excess in Bengal. An interesting feature in the temperature conditions of February was the unusually low temperature experienced in Gujarat, shown in both maximum and minimum temperatures. Two well-marked cool waves crossed India during the month of March, the first from the 7th to the 12th and the second from the 23rd to the 30th. The principal abnormal features in the mean temperature of the month were an excess of temperature in the West and Central Punjab, Sind and Gujarat and a defect in the east of the Gangetic Plain, Chota Nagpur, the Central Provinces and the south-east of the Peninsula. The variations from the normal were shown chiefly in maximum temperature in the areas of defective temperature and in Sind and Gujarat, and in minimum temperature in the West and Central Punjab. Maximum temperature was in moderate to large excess in North-West Burma and the adjacent districts of Assam and Bengal. In April temperature was below the normal in Baluchistan, and a considerable part of North-West India, especially in Baluchistan, the Punjab and the west of the United Provinces, and the defect was shown in both maximum and minimum temperatures. The variations from the normal on the mean of the whole month were comparatively small and unimportant in other parts of the country. On the 11th a cool wave appeared in the extreme north-west, but it did not influence the temperature outside of the Punjab to any important extent. Another cool wave appeared over Baluchistan and the Punjab on the 17th and travelled across India as far as Bengal. A marked fall of temperature accompanying fairly general rain occurred on the 26th to 28th in the Peninsula, especially in the south. In May the mean maximum temperature for the whole month was slightly to considerably below the normal over the greater part of the Punjab and slightly below in parts of the interior of the Peninsula. It was slightly to moderately above the normal in Sind, the South-west Punjab, and the Central India Plateau. Minimum temperature was also in excess over the same region and in defect in parts of the Punjab and of the interior of the Peninsula. From the 5th to the 10th minimum temperatures from 10° to 23° below the normal were recorded in Upper India. Maximum temperature was still more largely below the normal during this period, and at several stations on the 5th to the 7th was from 20° to 27½° below the normal. The highest maximum temperature recorded during

the month was 123° at Jacobabad on the 30th, which has only twice previously been equalled in the month of May. In the month of June temperature was in very general excess, due chiefly to the failure of the monsoon to extend into the interior districts. Both maximum and minimum temperatures were in moderate to large excess over the central parts of the country, the excess in the former being most strongly marked in the Gangetic Plain, the eastern states of Central India and Chota Nagpur. The highest maximum temperatures recorded this month in the divisions of Bengal, Bihar, Chota Nagpur and the United Provinces were the highest on record for June. Both maximum and minimum temperatures were below the normal on the mean of the month in Baluchistan, Afghanistan and the Kashmir mountain districts, probably due to late snow on the higher ranges of the Himalayas. Rain was again in general defect in July and temperature was again in moderate to large excess over the greater part of the country, the area of largest excess, however, being this month shown further west, chiefly over the Central India Plateau and the Gangetic plain, where both maximum and minimum temperatures were in moderate to large excess. On the 6th Jacobabad reported a maximum temperature of 126°,—a temperature which has been recorded only once during the past 25 years, *viz.*, on the 13th June, 1897. In August rainfall was light in North-West India and the south of the Peninsula and was fairly continuous elsewhere, especially in the central parts of the country. The variations from the normal of temperature were closely related to the distribution of rainfall. Both maximum and minimum temperatures were in slight to considerable excess over the greater part of North-West India and to a smaller extent in the south of the Peninsula ; and maximum temperature was below normal in the central parts of the country. Rainfall was lighter than usual in September and temperature was in general excess, the excess being shown chiefly in maximum temperature. During the latter half of the month the excess in maximum temperature was considerable to very large in Rajputana, Gujarat, Khandesh and the Deccan. Unusually high temperature continued in October, November and December, and the excess was shown in both maximum and minimum temperatures over the greater part of the country, especially in North-West India. Unusually fine weather prevailed in November and December in Persia and Baluchistan, and no depressions entered India from the west during these months.

The mean temperature for the whole year was in excess in nearly every division. The variation from the normal was less than 0·5° and hence temperature was practically normal in the Himalayas, the Gangetic Plain, Orissa, the Central Provinces (south) and Berar. The largest excess was shown in Eastern Rajputana and Central India (2°) and the Nerbudda Valley (1·9°). For the whole of India the excess averaged 0·6°.

Pressure varied by only small amounts from the normal during the greater part of the year. In March and September it was, however, in slight to moderate excess in all divisions, the excess for the whole of India averaging about ·045° inch during these two months. Pressure was in slight defect in August and October. For the whole year the variation from the normal was only +·005 inch.

Relative humidity was on the mean of the whole year and for the whole of India slightly below normal. It was in excess in January and February and in general defect from June to the end of the year. August was the only month during this period that showed a slight excess. The largest defect during the monsoon period occurred in Eastern Rajputana, Central India, the Nerbudda Valley and Chota Nagpur ; and during November and December in the Nerbudda Valley, the Central Provinces (south) and Berar. The excess in January and February was most marked in Chota Nagpur, East Rajputana, Central India, the Gangetic Plain and the Punjab Plains.

Cloud was in moderate excess on the mean of the whole country in January, February and April and in moderate defect in June and September. It was considerably below the normal in North-West and Central India during the months of June and September.

The rainfall of the whole year was in defect in all divisions except Lower Bengal, Malabar and Ghats, the Carnatic, Pegu and Tenasserim. On the mean of the whole area the annual rainfall was 3·92 inches in defect, or excluding Burma, 4·13 inches. In 1900 the defect for India, excluding Burma, was 0·57 inch and in 1899 11·14 inches. The largest defect in the annual rainfall of 1901 occurred in Gujarat (17·82 inches) and East Rajputana (12·24 inches).

The rainfall of January and February was in general excess except in East Bengal, Assam, Gujarat, Sind and Cutch. During the hot weather months less rain than usual

was received in nearly all divisions, the defect being most marked in East Bengal, Assam, and the Eastern Himalayas. Rainfall was heavier than usual in a few divisions, the excess being largest in the North Deccan and the Nilgiris. During the monsoon period of June to October rainfall was again in general defect, the only parts of the country where rain in excess of the normal was received being Tenasserim, Arakan, Assam and East Bengal, and the Nilgiris. The north-east monsoon rains during November and December in South India were generally heavier than usual, the largest excess occurring in Malabar and Ghats. Rainfall during these two months was also heavier than usual in Assam and East Bengal, Lower Bengal, Eastern Himalayas, Orissa and the Northern Circars.

European Troops.

Sickness and Mortality in 1901.—The health of the European army of India was better than in the previous year, though the invaliding ratio was greater.

Years.	Average Strength.*	Ratio per 1,000 of Strength.				
		Admissions into Hospital.	Constantly Sick.	Deaths.	Invaliding.	Total Loss.
1896–1900... ...	66,974	1,339	86	17·08	33	50
1900	60,553	1,143	72	14·62	33	48
1901	60,838	1,104	67	12·38	39	51
1891–1900... ...	68,224	1,399	87	16·21	29	45

*The quinquennial and decennial ratios are, of course, worked on the total strength of the lustrum and decade respectively.

The chief causes of admission were ague and venereal disease. Among the diseases with increased admission rates were influenza and respiratory diseases. On the other hand, the admission rates from cholera, small-pox, remittent fever, enteric fever, ague, dysentery, and venereal disease were lessened. Ague and venereal diseases caused respectively 27 and 25 per cent. of the total sickness.

The chief causes of death were enteric fever and abscess of the liver. Among the diseases with increased mortality were circulatory diseases, respiratory diseases, and dysentery. On the other hand, the mortality from cholera, diarrhœa, ague, enteric fever, remittent fever, hepatic abscess, and tubercle of the lungs was lessened. Enteric fever caused 27 per cent. of the total deaths, and hepatic abscess 11 per cent.

The chief causes of invaliding were, in order, ague, secondary syphilis, debility.

The chief causes of admission in the China Expeditionary Force was venereal disease, of which 56 per cent. was gonorrhœa.

Commands and Stations.—Madras was the most unhealthy of the four commands, Bombay coming closely next, and both being less unhealthy than in 1900. Bengal had the highest mortality from cholera, small-pox, remittent fever, dysentery, diarrhœa, and hepatic abscess ; Punjab the highest from enteric fever, ague, heatstroke, tubercle of the lungs, and pneumonia. The highest death-rates among stations of over 100 strength were those of Barrackpore, Deesa, Ahmedabad, Murree, Naini Tal, and Poonamallee, the three last being depôts for men sick or convalescent. All had higher death ratios than in the previous year. Dysentery was the chief factor at Barrackpore, and fevers at Deesa. The highest death-rates in stations of over 1,000 strength were at Ferozepore and Umballa, enteric fever being the chief cause in both cases. The ratio of Ferozepore was somewhat lower than in 1900, that of Umballa considerably higher.

* Worked on the aggregates.

Geographical Groups.—The most unhealthy geographical groups in 1901 were Burma Inland and Bengal-Orissa, the latter being also more unhealthy than in 1900. Burma coast had the highest admission ratios from influenza and venereal diseases ; Burma Inland the highest from ague and pneumonia ; Bengal-Orissa the highest from tubercle of the lungs, dysentery, and abscess of the liver ; Indus Valley the highest from small-pox ; Central India the highest from enteric fever, remittent fever, and diarrhœa ; Southern India the highest from simple continued fever ; and the Hill Stations the lowest from ague and venereal disease. The only point in which the decennial relations, described in last report, correspond with the above is the supreme height of the dysentery admission ratio in Bengal-Orissa.

* Worked on the aggregates.

Influenza.—The absolute and proportional amounts of influenza rose greatly. The admissions began to rise in February, reached their maximum in May, and rose again in December. For the 12 years that the disease has been epidemically present in India the maximum month is April, and the minimum August. As compared with 1900, Group VII was the only fresh one affected ; Group II escaped in both years ; while in both all the other groups recorded admissions. Thirty-three stations returned cases, against twenty-two. The highest numbers were at Rangoon, Nowshera, and Kuldunnah. The disease was generally mild in type, and only one death was returned. It is said to have been severe at Roorkee, and to have caused much debility at Kuldunnah. The researches of Onorato on the resistance of the influenza bacillus to physical and chemical attacks, show, among other things, that under laboratory conditions it is very susceptible to drying and to the action of carbolic acid and some other common disinfectants.

Cholera.—The amount and proportion of cholera was much less than in the previous year, the admissions having fallen from 107 to 12, and at no station were there more than three cases. It is generally mentioned that the disease was present in the neighbouring city or bazaar, but the exact origin does not seem to have been traced in any case. At Poona the two men first attacked were in Ward 1 of the hospital, and the third was attending on the first after he had been removed to another ward.

Small-pox.—The admission rate from small-pox was only a half of what it had been in 1900, but the death-rate remained the same ; the admissions and deaths being 20 and 3 against 36 and 3. Jubbulpore had 3 admissions and 2 deaths, and no station had more. Most of the cases were mild in men who had been vaccinated and revaccinated, or vaccinated and unsuccessfully or inefficiently revaccinated. A confluent form of the disease occurred at Rangoon in the person of a man who had not been vaccinated for 11 years and had not satisfactory marks of protection. At Jubbulpore the men were on duties which brought them into contact with natives ; and the disease was generally present in the city or bazaar.

Ague, remittent fever, simple continued fever, Malta fever.—Ague gave rise to nearly 27 per cent. of the admissions from all causes. Both the admission and the death-rates were lowered. The most malarious month for India was October, but for Burma Inland, which was the most malaricus group, it was November. The most malarious stations were Fort Dufferin, Fcrt Lahore, and Meean Meer ; and then Nasirabad, Ferozepore, and Delhi. The fever at Fort Dufferin is said to have been milder than in 1900, and Mandalay Hill continued to be more healthy than the fort. The malariousness of Fort Lahore is attributed to the lowlying marshy ground on the bank of the river near the fort. Men from Barrackpore and Delhi are said to have increased the ague admissions at Nasirabad ; but in September anopheles was found in swimming baths, garden tanks, gumlahs, drains, pools, ghurrahs. Measures were taken against the anopheles, and quinine was issued prophylactically, but the effect was "not very apparent." Much of the sickness at Ferozepore is said to have been connected with the previous year's outbreak. Fever at Delhi was most abundant at the season when pools had formed in the river bed, and anopheles was frequently found. The use of kerosene is said to have produced no appreciable difference ; but, as far as the report shows, it does not seem to have been carried out with much thoroughness. Meean Meer was examined by the Royal Society's Malaria Commission in December, who found that the bearer of the infection was the *Anopheles culifacies* bred in the numerous irrigation channels, and made suitable recommendations. Many admissions were recurrences, and regiments coming from unhealthy stations raised the numbers in some stations where the disease was not naturally very prevalent. At Peshawar the ague was ascribed to inordinate irrigation ; while at Kirkee the catchpits and unlined drains near barracks, were considered to have been more to blame than the irrigation. At Rawalpindi and Dinapore there were plenty of anopheles breeding pools ; and at Roorkee these mosquitoes were found to be breeding in the fire tanks. No anopheles could be found in No. 2 district at Mhow, though it was present in a village half a mile away ; and the artillery at Fort Syrian suffered much more than the troops in Rangoon itself. At Colaba, where the anopheles is said to be unknown, the garrison artillery had no fever ; but they suffered after going to Middle Ground Fort, where anopheles is frequently found. There is said to have been no local ague at Mount Abu, the rainfall having been 47 inches less ; and anopheles, so common in the previous year, was hardly to be seen. The diminution at Aden was ascribed to the scanty rainfall, to the non-occupation of the isthmus position, and to the greater attention paid to the destruction of anopheles. At Mallapuram patients

had prolonged quinine treatment, and while in hospital used mosquito curtains, hollows were drained and levelled, waste or stagnant water was not allowed to remain in the barracks, and some pools were treated with kerosene. Anopheles larvæ were found at Neemuch in the puddles and hoof marks near the wells, in the tatty and garden tanks, in catchpits and drains, and in the edge water of a nullah, all near the hospital or barracks ; and measures were taken accordingly. Though common in the previous year, anopheles was rare in 1901 ; and it was supposed that the larvæ might have been washed away by the floods in 1900. In Amritsar anopheles was plentiful, but it was difficult to find its breeding places. Pools were drained and filled in at Deesa, covers were provided for the water chatties, and disused wells were kerosened. The stagnant pools of Sialkot were attended to ; one near the military prison was levelled, "and ague cases appear to be now less frequent." At Nowgong great care was given to filling up stagnant pools and holes near barracks, and to removing tins, &c., likely to harbour the larvæ ; and it is said that there are now fewer mosquitoes and less malarial fever among the European troops. Though the prophylactic issue of quinine was probably universal, or nearly so, only sixteen reports mention it. Seven say that the effect was good ; one that the disease was made milder but not prevented ; one that ague held off as long as the quinine was given, but began to occur again within a week after it was stopped ; two that there was no appreciable effect ; and one that in spite of it there was more ague than in the previous year. Probably, if medical officers were keen about the matter, they would say more about it in their reports.

There was also a great decrease in remittent fever. The maximum month, like that of ague, was October ; but there was another maximum in June, to which ague had nothing corresponding. The highest admission ratios were at Mhow, Mount Abu, and Shwebo.

The admission ratio from simple continued fever was the same as in the preceding year. The most frequent causes assigned for the attacks were heat, work in heat, exposure to the sun, errors of diet, chills. Some of the cases are said to have been possibly enteric fever, while others were distinguished from that disease only by the negative result of Widal's reaction or by the sudden permanent fall of the temperature. Two of the cases were thought to have been possibly Malta fever, and in one station dengue was suggested. Benares returned neither simple continued nor enteric fever.

Three cases of Malta fever were returned from Meerut, and one each from Subathu and Poona ; the diagnosis in most, if not in all, being confirmed by the serum reaction. Six cases of accidental infection through minimal inoculation have lately been published by Wright and Windsor as having occurred at Netley ; and they notice also two other similar cases, occurring respectively at Haslar and in the Philippine Islands.

Enteric fever:—*Water and Milk.*—The fact of the frequent connexion between the ingestion of drinking water and enteric fever is acknowledged, and appears to be established ; but the exact relation of the water to the morbific agent is still involved in obscurity. From an examination of the records of 638 epidemics and 12 single cases, contained in the literature of 14 countries of the world, Schüder found that 70 per cent. had been referred to water, only 17 per cent. to milk, and the still lower per cent. of from 0·2 to 3·5 to other causes ; and concludes that the cause of the disease must be combated in the first place in water, and that when that has been done, the greater part will have been done. Corfield, too, in his Milroy lectures, has collected from all parts the powerful evidence which points to water as the chief vehicle of the infection. Yet it has been found more difficult than ever to recover the specific microbe from suspected water, the progress of knowledge having led investigators to be less easily satisfied in the matter of identification. In fact, Sims Woodhead, agreeing with others as to the difficulty of finding the bacillus in water, states that he has never succeeded in isolating it therefrom, except when he had previously placed it there himself. It has been pointed out that unless the specific pollution is continuous, it is extremely unlikely that enteric bacilli will be detected in a water if more than a week has elapsed since the actual pollution occurred. As the incubation time of enteric fever is usually over a week, the bacillus will have vanished by the time suspicion is thrown upon the water by the occurrence of cases. In all cases it is necessary to examine a considerable quantity of the water, and that the examination should be systematic and periodic, "the variations in the composition and flora being the surest signposts of danger." Another explanation which has been thought of is that the enteric bacillus may change its typical characters when

living in water. Hence the attention which is directed to the enteric-like bacilli of water, as distinguished from those of more frankly colonic character. Thus Vaughan believes that a water containing the colon bacillus alone does not cause enteric fever, and that the more enteric-like the germ is, the more likely is the water containing it to cause enteric fever; and he has no hesitation in condemning waters which contain enteric-like bacilli. He is one of those who have never succeeded in finding in any sample of water a typical enteric bacillus, and who do not believe that it preserves its typical characters for any length of time when growing in water. Some observers from actual practice have reported that it is not safe to trust alone to the method of von Drigalski and Conradi, which consists of cultural separation in a special medium, and then confirmation by a highly diluted enteric serum; but that the colonies apparently identified as enteric must be submitted in addition to all the usual tests. It is frequent in India as elsewhere to find in water bacilli which, while giving all the cultural reactions of the enteric bacillus, refuse to be aglutinated by enteric serum. With regard to such Bancel suggests that in order to be able to pronounce on their nature the observer should make a series of cultures, and see whether they do not sooner or later become agglutinable; and points out that enteric bacilli from blood, pus, &c., are only slightly agglutinable, but become more so by cultivation on artificial media. From his suggestion that the agglutinability may vary inversely to the virulence it follows that such an enteric-like bacillus of water, which possesses all the classical characters of the enteric bacillus except its agglutinability, may in reality be the true bacillus in its most virulent form. On the other hand, it must be remembered that, according to present knowledge, clinical enteric fever may be caused by more than one bacillus, that more than one disease is included under the clinical name "enteric fever," a fact which explains some of the clinical failures of Widal's test. And Sion and Negel have actually described an outbreak of waterborne enteric-like fever caused by a non-Eberthian bacillus. Neumann enunciates a peculiar hypothesis, that drinking water does not convey the bacillus, but certain fluid bodies which enable the enteric-like bacilli, everywhere present, sometimes inside the body as well as outside, to become true enteric bacilli. Sims Woodhead believes that with our present methods more is to be gained by a general bacteriological examination than by an examination for any special species, and lays far more stress on the departure of water from its normal bacteriological standard than on the appearance of any special set of organisms, though the appearance of any fresh set of organisms is, of course, a definite indication that the water is departing from its normal bacteriological standard. After all, even if the enteric bacillus itself cannot be found in a suspected water, it is sufficient, as Houston among others points out, to show that microbes indubitably of intestinal origin are present in a water, to condemn it; because they are apt, of course, to be accompanied by pathogenic germs. Here again doubt has arisen as to which germs are of indubitable intestinal origin. Some like Chick have minimized the distribution of the *Bacillus coli*, for example, while others find it everywhere; and this disagreement seems to depend upon a difference of opinion as to what is and what is not a *Bacillus coli communis*. There is, however, a general agreement that the number and not the mere presence is to be regarded, that the source which supplies the colon bacillus to the water should be searched for, and that special suspicion should attach to a varying content. Pakes stated in 1900 that water which contained *B. coli* in 20 cc. or less should be condemned, that if the *B. coli* were only present in from 50 to 100 cc. the water should be looked upon as slightly suspicious, and that if that bacillus were only present in greater quantities than 100 cc. the water was probably safe. Horrocks considers that water which contains *B coli* so sparsely that 200 cc. have to be tested to find it, is probably polluted with sewage, but the contamination is not of recent date. Houston finds that streptococci are absent from 10 cc. (or more); *B. coli* from 1, 10, it may be 100 cc. (or more); and *B. enteritidis sporogenes* from 100 to 500 cc. (or more) of pure waters: that is, these microbes are altogether absent or relatively so from pure waters; that the presence of streptococci is to be thought of as indicating extremely recent, and of *B. coli* less recent but still not remote pollution of animal sort, but that the presence of *B enteritidis sporogenes* cannot be considered to afford evidence of pollution bearing a necessary relation to the recent evacuations of animals; that the presence of streptococci in any number in a water-supply points not only to recent animal pollution, but also implies that the antecedent condition—conditions intervening between the period of pollution of the water and the time of collection of the sample—could hardly have been of so unfavourable a character as to destroy the vitality of seemingly more hardy microbes—for example, the enteric bacillus, though quite the same cannot be said for the *B. coli*, since *B. coli* is a more hardy germ than *B. typhosus*. Firth is of opinion that the

presence together of streptococcus and *B. coli* is an indication that the water has recently been contaminated by sewage and is unfit for use. Chick's experiments led her to believe that the colon bacillus is much less ubiquitous than has been supposed and that its presence indicates recent pollution. On the other hand, Papasotirin who has found *B. coli* in dough and in various unground cereals and pulses, considers that the presence of some colon bacilli in water is of no significance, but that a great abundance makes one think of contamination by fæcal matter; though it may also be connected with the putrefaction of vegetable matter. Irons cautions against trusting to neutral red for the detection of the colon bacillus in water, since the reaction is given under the conditions of the test by a number of other water organisms which no classification however liberal would place in the colon group. The propriety of judging different kinds of water by different standards is insisted on by Savage, allowance being made for an upland surface water, for example, as compared with a spring water. Waters which show no colon bacilli in 50 cc. are, according to him, of a high degree of purity. Some, like Meusburger and Rambousek, are content to have as sole criterion the colon bacillus as such; but Horrocks, as quoted in last report, has endeavoured to distinguish colon bacilli derived from a case of enteric fever from colon bacilli of ordinary provenance. The technique employed by Horrocks is, however, considered by C. Fränkel to be not quite beyond reproach. In the United States, in river water considered on inspection to be unpolluted, Smith and Brown found the numbers of colon bacilli to vary between 9 and 5 per cc.; and Jordan remarks that as there are no methods in common use that are universally applicable to their direct detection, the fate of typhoid germs introduced into a stream or lake must be determined by inference; and that the best index we can secure at present for gauging the probable continuance of vitality of the enteric bacillus in running water is the information derived from the fate of the colon bacillus. Aldridge, after remarking that the vitality of *B. typhosus* in water is not great, and that when enteric fever is almost continuously present there must be repeated infections from fæces or urine, which can hardly be conceived toaffect well-protected pipe supplies, goes on to say that in combating enteric fever in tropical places it is not sufficient to obtain a water pure at its source, nor even to purify a doubtful water, but that the chances of its contamination are as great—in many cases greater—as at its source. Caink found that the enteric fever rates in towns supplied with filtered river water were much lower, generally speaking, than those in towns supplied from artesian wells and mountains. The somewhat similar results of Saltet in Holland are discussed by Corfield in his Milroy lectures. In the sanitary history of cities, says Osler, it has been amply demonstrated that an abundant and good water-supply, though of the first importance, is not enough to reduce the death-rate from typhoid fever to a minimum. He gives instances where the high death-rate from the fever persisted after the introduction of a good water-supply until a sewage system had also been introduced. In America, as in India, instances have been noticed where troops using the same water-supply as the civilian population suffered from enteric fever, while the latter escaped entirely or almost entirely. Schüder has shown that the bromine process of Schumburg, so much praised at one time, is practically useless for the sterilization of water, as regards the germs of cholera and enteric fever; and Engels from his experiments concludes that of all the chemical means of water sterilization hitherto invented, with the possible exception of ozone, not one is really trustworthy. The practical use of ozone in the treatment of drinking water has been studied by Ohlmüller and Prall, who found that it gave a better general result than sand filtration, and that the cholera and enteric fever bacteria were destroyed. Schüder and Proskauer in a still more recent research formed a favourable opinion of ozone, but pointed out imperfections in the methods of Ohlmüller and Prall. The danger of trusting to aërated waters as safe, especially in times of epidemic enteric fever, has been emphasized by Chantemesse and others, as the bacilli retain their vitality in such waters for days and even weeks. A résumé of knowledge as to outbreaks caused by milk, and of the behaviour of the enteric bacillus in milk, has lately been given by Corfield. Osler remarks that one or two typhoid bacilli in a glass of water may be, probably often are, taken with impunity by an individual not specially susceptible, but a few in water used to rinse a milk can or jug would find in the milk such a suitable medium for growth that in twenty-four hours the food would be highly infective. So also Fulton shows that milk infection means large dosage and greater percentage of attacks. Schüder speaks of milk as a very dangerous spreader of the infection, because it is a good nutrient medium for the bacillus, and because infected milk is apt to be delivered to a large number of households. It is stated that enteric bacilli retain their vitality in boiled milk for as long as three months or more.

Soil. Dust. Flies. Clothes.—No single fact, says Osler, has been more clearly brought out than the intimate association between sewage polluted soil and typhoid fever: wholesome healthy water is not alone sufficient to abolish the disease; but healing of the sickness in the soil, purifying it by proper drainage, is at once followed by a remarkable fall in the death-rate from typhoid fever: this has been strikingly shown in many cities: the local conditions permitting the disease to be endemic throughout the year relate unquestionably to the persistent pollution of the soil: the presence of typhoid fever in a city means bad drainage, or polluted water-supply, or both. With regard to the cases from time to time reported of the occurrence of outbreaks of the fever on the so-called virgin soil of remote uninhabited places, Munson suspects that the soldiers carried the infection with them in their own bodies (excreting it in their urine), on blankets, &c. Some of the most important instances of the connexion of enteric fever with soil infection have been recently collected by Corfield; and Schüder in treating of the same subject, points out the danger of soldiers and workmen, who have to clean their own boots and often eat without washing their hands, of the infected earth which adheres to the boots. The general result of Sidney Martin's late researches was to show that the enteric bacillus has commonly only a short existence in the soil, and that it is destroyed by the products of the putrefactive bacteria which exists in most cultivated soils. As Houston says, the general tendency is for the more hardy soil bacteria to oust the sewage microbes in the struggle for existence: *B. coli* and allied forms introduced with the sewage become greatly reduced in numbers, and their presence in a soil in any considerable amount is taken as suggesting pollution of comparatively recent date, the presence of streptococci in soil is another good indication of of sewage contamination, and, as these organisms dissappear very rapidly, of its extremely recent occurrence. E. Pfuhl found the enteric bacillus to survive close under the surface of damp garden earth for 88 days, in loose pretty dry sand for 28 days. The observations on this point of many observers are summarized by Gotschlich. The experiments of Firth and Horrocks showed them among other things that there is no evidence to prove that the enteric baccillus when placed in soil displays any disposition or ability to increase in numbers or grow upwards, downwards, or laterally; that it is able to asume a vegetative existence in ordinary and sewage polluted soil and survive therein for varying periods amounting in some cases to as much as 74 days; and that an excess or deficiency of moisture in soils appears to be the dominant factor affecting the chances of survival of the enteric bacillus, or at least the possibility of recovering it. The moral which V. Poore draws from their experiments is that care and attention make the practice of burying excreta in the earth practically safe, the cultivation and cropping of the land being duly regarded as part of the process. Munson thinks the dry earth system likely to aid in the spread of enteric fever; and that, though the bacillus is destroyed by dessication in a short time, it may long retain its vitality in relatively dry material, and find in dust and wind an excellent vehicle for its diffusion. To show that some of the dust carried by the wind actually does come from the latrines, Powell records having had to abandon dinner on the veld, owing to a dust spout, which had first passed over the trenches, covering the food with dust and toilet paper; and remarks that many a time food must have been eaten covered with dust from the same quarter, when there was no telltale paper to betray its origin. So Osler mentions the danger of dust sweepings from unwatered streets reaching uncovered milkpans. Munson mentions that Tryde and Salomonsen found enteric bacilli on the floors of a barrack in Copenhagen, Uptadel at Augsburg, Birch-Hirschfield at Leipsig, Chour at Jitomir. On the other hand, the opinion given in Nothnagel's Encyclopedia is that the dissemination of the enteric bacillus in the dry state, attached to particles of dust, through the air is possible, but not common. Firth and Horrocks found that from an ordinary soil allowed after inoculation with the bacillus to become so dry as to be readily blown about as dust, the enteric bacillus can be recovered up to and on the twenty-fifth day; and that enteric infective material can be readily translated from dried soil and sand by means of winds and air currents. The same experimenters found that the ordinary house fly can convey enteric infective material from specific excreta or other polluted material to objects on which they may walk, rest, or feed; but that it has not been proved that the enteric bacillus passes through the digestive tract of the fly. During three years in the United States, Howard and his assistants made a collection of all the insects found on or breeding in human fæces; 44 beetles, a number of hymenoptera, and 77 flies. In kitchens during two summers they caught 23,087 flies, of which 98·8 per cent. were *Musca domestica* and 1·2 per cent. of various other kinds, but none of the kinds which are most frequently found on human fæces. Howard, however, points out that though the common fly usually deposits its eggs in horse dung, it frequently lays them in human fæces; so that it is dangerous to

have human fæces in the neighbourhood of kitchens and dining rooms. Corfield and others give instances of infection contracted from soiled clothes, or warn against the danger ; but Collie brings forward examples of the greater danger undergone in visiting a patient than in washing his clothes. On pieces of uniform cloth soiled with emulsion of the enteric bacillus Firth and Horrocks found the bacillus capable of detection up to from 74 to 87 days ; and on uniform cloth soiled by enteric fæces up to from 9 to 17 days.

Enteric fever—direct infection.—That enteric fever is frequently communicated by personal intercourse is an opinion which has steadily been gaining ground of late years. This was found to be an important factor in the causation of the fever in the American military camps ; and in a German official military report it is stated that in enteric fever the conveyance from man to man, from patient to attendant, plays a not unimportant part. Corfield and also Munson point out that the incidence of the disease to strength is higher among attendants than among patients in the hospital or soldiers in general. Statistics for nurses are given in Nothnagel's Encyclopedia, though it is expressly pointed out that the disease is not contagious in the old sense of the term. In the Prussian army in 1897–98, 30 attendants and 11 patients in hospital for other diseases were attacked ; and Schüder speaks of 35,647 cases of enteric fever with 1,179 cases among their attendants. Eschricht gives a series of five cases, in which each successive person attacked had been attending on the one before ; and Krieger reporting on the work of Koch's enteric fever commission mentions that direct infection was found to be more common than had been supposed, and to be the chief means by which the disease was spread. Finally, of some importance are the laboratory cases of Fürnrohr and of Klinger. Fürnrohr fell ill three weeks after making an enteric post-mortem examination, and was supposed to have become infected through splashing in cleaning the intestine, or from not having succeeded in cleansing his hands thoroughly. During an experiment an accident caused infective material to splash up into the faces of Klinger and his assistant, and both were in due course attacked by the disease. It has long been known or suspected that the disease may be infectious in the incubation stage, that it is spread greatly by mild cases not diagnosed, and even that the evacuations of healthy people who have been in contact with the sick may contain the bacillus. Hurd speaks of a case in which the fever was moderate and lasted only 10 days, so that the disease was supposed to be a febricula ; but the Widal test was applied from time to time, and at last after 40 days the reaction became positive. In Alsace–Lorraine Koch's enteric fever commission have found the von Drigalski and Conradi medium combined with an improved agglutination procedure of great use in discovering mild unsuspected cases. Thus, in one place 73 cases were found where only 10–12 had been reported, and 53 of these were children under 16 years of age.

Enteric fever — the bacillus.— Courmont, in an article containing a résumé of previous work on the subject, records the finding of the bacillus in all of the nine cases which came under his observation in 1901, but does not venture to affirm that it would be found in mild or abortive cases. He found the bacillus as early as the fifth day, and in four cases before the Widal reaction could be obtained, and up to the end of the third week. The bacilli when recovered from the blood are generally but little agglutinable, but can be made more agglutinable by cultivation. There was no definite relation between their presence and the agglutinating power of the blood, which might be weak or negative. His results are confirmed by Busquet. Licht had positive results in 11 of 14 cases, Haslett in 17 of 24, and Menzer in one case. Haslett did not find the bacillus before the third or fourth day, but in three instances before the serum reaction was established. In two mild cases he found it on the 11th day. Schottmüller isolated it in 98 of 119, once on the second day ; Cole in 43 of 58. Widenmann recovered it from the roseola in 5 of 7 cases ; Seemann in 32 out of 34, in 8 before the serum reaction could be obtained. The total result of these and other observations is that the bacillus is discoverable in the blood in from 70 to 80 per cent. of cases. From a study of the literature, Schüder found that 19 observers had detected the enteric bacillus 177 times in the urine of 599 patients, 29·55 per cent. ; and he himself isolated it in 5 out of 22, 22·2 per cent. ; so that on the whole it may be said that it is to be discovered in between one-fourth and one-third of cases. Büsing records an interesting case of a soldier from China who went on giving out enteric bacilli in his urine for four months after he appeared to be in robust health. Urotropine was successful in clearing the urine, but the man was detained for a month more in hospital under constant observation before he was discharged cured. As an effective disinfectant for the voided urine Gwyn recommends the addition to it of one-fifth its volume of 1–1000 perchloride of mercury solution. By their new method von

Drigalski and Conradi succeeded in demonstrating the presence of enteric bacilli in the stools of patients at various stages of the disease, and in more than half the cases at a period when the Widal reaction was not yet established. Remembering Koch's positive results with the cholera comma, and his remarks on the importance of the matter, they examined the stools of apparently healthy persons who had shared the rooms of patients, and in the apparently normal stools of four of them found the enteric bacillus. Dieudonné isolated the enteric bacillus from the red sputum of a patient ill with enteric pneumonia. It remained present in the sputum far into convalescence and when the patient felt quite well, seven weeks after admission ; and he points out the importance of this feature, in which enteric pneumonia resembles plague pneumonia, for the spread of the disease. He and also Schüder quote previous similar observations by von Stühlern and by Edel, and two cases have quite recently been added by Glaser. Munson states that positive results have been obtained by Williams and others. In the course of an article on the gallblader complications of typhoid fever, Camac remarks that it is no longer a question of where the typhoid bacilli may be found, but where they may not be found in the body after infection; and Flexner gives a list of the various situations in which they may be found. Full details as to the work hitherto accomplished in the detection of the bacillus in the human body and its various excretions have lately been collected and published by Burdach.

Besides his earth results, already referred to, E. Pfuhl found the enteric bacillus to survive on linen 97 days, in iced water 26 days, in Seltzerwater 15 to 27 days, in milk 11 to 13 days, in butter and Gervais cheese 24 days. Firth and Horrocks report that the enteric bacillus is able to survive in surface soil an exposure to 122 hours of direct English sunshine extending over a period of 21 consecutive days ; and that from a piece of infected serge it is recoverable after the fabric has been exposed to 50 hours of direct English sunshine spread over a period of 10 days. According to MacConkey, not only is the enteric microbe unable to multiply in crude sewage and sewage effluents, but its presence can no longer be demonstrated therein after the lapse of 6–17 days. In cereal products Klein and Houston observed no tendency on the part of the enteric bacillus to multiply. Sedgwick and Winslow and also Brehme, experimenting with cold, found that there were always apt to be some survivors, even when the majority had been killed. Valentini concludes from his experiments that not only in human surroundings but in human bodies there exist enteric-like bacilli, which are usually harmless to the individual that shelters them, but under certain circumstances can acquire characters which make it impossible to differentiate them from true enteric bacilli, even by the serum reaction.

Enteric Fever without intestinal lesions. Non-Eberthian Fever (*Paratyphoid*).—From the rapid growth of the literature bearing upon non-intestinal forms of enteric fever Flexner judges that typhoid septicaemias will come to be regarded as by no means among the rarest manifestations of the disease. But at the same time the progress of bacteriological diagnosis has revealed the fact that a considerable number of cases which present the clinical picture of enteric fever are really caused by bacilli which are only enteric-like, not Eberthian ; and A. Fränkel might have gone further when he expressed his opinion that the belief in the unity of enteric fever is threatened, and that it looks as if from the bulk of so-called enteric fever at least one group would emerge, which is etiologically different from the majority. Others have expressed themselves in somewhat similar terms, and suggestions have appeared for the systematic searching out and study of such cases. Blumenthal has met with a fresh case of enteric fever in which there were no intestinal lesions, although Widal's reaction was positive and the bacillus was cultivated from the spleen and lymph glands. A case of enteric-like fever caused by a bacillus which appeared to be that of Gärtner has been brought forward by Craig and White. Johnston has published four cases of paratyphoid fever, with an analysis of all recorded cases, which shows that the gravity and mortality are less than in true enteric fever, and that there is an absence of intestinal ulceration. Such cases may also appear during enteric fever epidemics, but it is not justifiable to call all enteric-like cases in which the Widal reaction is negative, "paratyphoid," because the reaction sometimes fails in genuine enteric fever. For example, Hoffmann collects 178 cases of negative Widal reaction, and in eight of these the enteric bacillus was found. In two of Johnston's own cases a paratyphoid bacillus was cultivated from the blood, and in the other two the identification was effected by agglutination of Gwyn's bacillus or of the bacillus got from the first two cases. Widal's reaction was negative in all. Petruschky had a case in which the *B. alcaligenes* was isolated from the roseola, and has convinced himself that the colon bacillus, the *B. alcaligenes*, and perhaps others, may produce an infection very typhoid-like. An interesting waterbourne house epidemic was observed by Sion and Negel, in which the

symptoms were those of enteric fever. Two of the patients were a man and his sister, both of whom exhibited the Widal reaction. During life a bacillus was cultivated from the blood of the man, which proved to be neither the enteric bacillus nor a typical colon bacillus ; and after death there were found no intestinal lesions. In a military epidemic at Saarbrücken, reported by Hünermann, a bacillus belonging between the enteric and the colon bacilli was isolated from the stools and urine by means of von Drigalski and Conradi's method, and in most of the cases Widal's reaction was negative. The occurrence of cases clinically enteric fever, but not caused by the bacillus of Eberth, of course explains some of the negative results of Widal's reaction which have been reported as obtained in enteric fever ; and so far, as Gwyn points out, it enhances the value of the reaction.

Enteric fever—Incubation, &c.—In the case of Fürnrohr, referred to under direct infection, the period of incubation was three weeks ; in that of Klinger three weeks, and in that of his assistant, apparently infected at the same time, about five weeks. Palmer found that the incubation period of certain cases was five days. Corfield describes an outbreak in which Buchanan was able to fix the incubation time as 11 days. The experience of Timann has been that the roseola appears with great regularity from the twenty-first day after infection. In Nothnagel's Encyclopedia the incubation is stated to be usually one, two or three weeks, but sometimes longer. At Coblenz in a military outbreak Rieder fixed the time at 14 to 16 days in 80 per cent. of the cases. From an elaborate paper by Fulton, containing both his own experiences and those of others, it may be gathered that the limits observed were from 9 to 28 days ; except in the case of a child who drank infected milk only once, on the afternoon of the 19th July, and fell sick on the 24th, youth and a massive dosage causing shortening of the incubation time. In his account of a case in which there were three relapses, Warfield professes himself inclined to agree with Durham in looking upon the varying preponderance of varietal forms as explanatory of relapses. We are, says Osler, still really without full knowledge of the causes of relapse, but the frequent occurrence is a positive indication that immunity in typhoid fever is slowly acquired, and not reached at the period of apyrexia. In South Africa about 4·5 per cent. or more of Elliot and Washbourn's cases had had a previous attack, and one man died in his third. The highest percentage quoted in Nothnagel's Encyclopedia is that of Eichhorst, 4·2 (28 in 666), and he had observed cases in which there had been three and even four attacks.

Enteric fever in association with other diseases.—Finding that in a certain number of cases in South Africa already in hospital for dysentery enteric fever developed, Rolleston concluded that the diseases had been contracted together, but that the incubation time of enteric fever is greater than that of dysentery. In the same country Elliot and Washbourn observed 21 cases of enteric fever associated with dysentery in the attack, or shortly before or after ; and Morris noted that as many seemed to have the dysentery after as before the enteric fever. The bacillus of Shiga seems to be a near relation of that of Eberth. Osler states that Da Costa has collected 22 cases in which the association of abscess of the liver with typhoid fever seemed beyond doubt : that the Munich statistics of 2,000 enteric fever post-mortems give 12 ; that these Munich statistics perhaps include those of Dopfer, who found 10 in 927 ; and that abscess of the liver is also sometimes secondary to the complications of enteric fever, such as bone disease, laryngeal perichondritis, &c. Lyon gives notes of 30 cases of true combined typhoid and malarial infections, and refers critically to other reported cases ; and Osler in Nothnagel's Encyclopedia reports only three out of 1,100 cases of enteric fever treated in the Johns Hopkins Hospital. But in such countries as India similar cases may probably be common. By Fiocca is published a case in which the haemamoeba was present in the blood before the onset of the enteric fever, during the interval between the original fever and the relapse, and after the relapse had subsided, but not while the enteric fever was actually in course.

Enteric fever—susceptibility and conducive causes.—The board which investigated the outbreaks of enteric fever in the American army during the war with Spain believed that from one-fourth to one-third of the individuals in a regiment were susceptible. Munson and also McCulloch have each treated of the greater incidence of enteric fever among cavalry men than among men of infantry regiments. The latter surmises that possibly the unsterilized water used may contain enteric bacilli, which passing through the horses' bodies may contaminate the ground and litter, and also that the men are in the way of temptation to drink the impure water. Corfield states that overcrowding appears to have less influence on the spread of enteric fever than of any of

the other contagious fevers, owing to the fact that the disease appears to be less directly spread from person to person. But the opinion is gaining ground that personal infection and therefore overcrowding, are very effective, and Corfield himself gives an instance in which Buchanan thought overcrowding had had a good deal to do with the spread of the fever. In the American camps also it was considered to have been a potent factor. The effects of overcrowding and fatigue are also noticed by Munson. A great deal has appeared in the medical papers during the course of the South African war on the subject of enteric fever among troops on active service ; and a fresh discussion has lately taken place in the Medical Society of London, the outcome of which is that if the water-supply were in the first place protected and excreta disinfected, a great deal, but not all, would have been done to diminish the scourge.

Enteric fever—Prevention. Inoculation.—Corfield summarizes cases which have cast suspicion upon sewer air, and Munson states flatly that the disease may be transmitted by aërial infection from drains, water-closets, latrines, dust-heaps, &c. Corfield and also Schüder have pointed out generally and in detail the particular defects of insanitation which have been connected with actual outbreaks, and the general and some of the particular measures which should be taken to remedy them. Corfield quotes Buchanan as saying that it is the purification of the atmosphere from decomposing organic matters which has been most uniformly followed by a fall in the prevalence of enteric fever. The first thing, acccording to Schüder, is to protect the water, the second to destroy infection the moment it leaves the body of the sick, and the third to protect the attendants by inoculation. Reincke judiciously remarks that even when the water is infected every case does not arise from that ; but some from direct personal infection, some from secondary, tertiary, or more remote foci of infection developed in a latrine, on soiled linen, in a well, in a dairy, in a kitchen, in a gelatine pudding, &c. Agreeing with Duclaux, Schüder, and others, Firth and Horrocks insist that for a proper exercise of preventive measures attention must be concentrated on the dejecta the moment they leave the human body, because once the specific organisms become disseminated in nature, the task becomes stupendous on account of the number of the paths of infection. They point out the defects of the dry earth system in use in India, advocate the use of trough water latrines, and discourage the introduction of biological methods of sewage disposal. But the Government of India will not hurriedly give up the trenching system on account of evidence brought forward which probably only touches the results of bad trenching. Krieger, as has been mentioned, notes the opinion formed by Koch's German commission as to the necessity for greater attention to diagnosis, isolation and disinfection ; and Munson gives the practical rule that convalescent patients should not be permitted to return to duty or quarters till the bacillus has been absent from the urine for a week. The whole matter sums itself up as an effort to secure cleanliness in air, soil, and water. Inoculation has been treated of by Crombie and by Wright from a statistical point of view, while Besredka has suggested a new method of preparing vaccines.

Enteric fever—Opinions of medical officers.—The Medical Transactions of 1901 are even more barren than their predecessors of wholehearted or plausible attempts to explain the origin of outbreaks of enteric fever. Recognizing more than ever how little is really known of the natural history of the enteric bacillus, medical officers seem to have come to the conclusion that the less they say, the less they are likely to be wrong. Nearly forty of them state that they could find no cause for the cases which occurred. Of course, as usual, and especially in connexion with the movement of troops, many cases originated elsewhere than in the stations in which they were treated. About eight of the men attacked had very recently landed from England, and two cases occurred, at Colaba and Deolali, in men just off the ship, the disease appearing to have been contracted before arrival in India. Of Agra it is stated that recent arrivals in the station were more liable than residents, irrespective of their length of Indian service. At Quetta two-thirds of the cases occurred in the Cheshire Regiment, which arrived in that station during the year, and no particular barrack-room was affected. At Mhow the preponderance of cases was in the 20th Hussars, and the medical officer considered that the hygienic arrangements of the regiment must have been seriously at fault, nearness to the bazaar being perhaps a factor. The men of the Dorset Regiment at Ferozepore were supposed to have owed their particular liability to their weakly condition from the effects of malaria. Out of 21 cases at Meerut, 13 occurred in the 15th Hussars, but no cause was discovered for the greater incidence in that regiment. Several medical officers mention that the cases occurred in a scattered manner in various corps and barracks. No. 4 British cavalry barrack at Lucknow had a disproportionate number of cases ; but no sanitary defect could be found

in it, and the medical officer suggests that the men may have together frequented some place outside barracks, and got the infection there. At Ferozepore the bazaar was considered to be indicated as the source, because, while the rank and file were attacked, the staff remained free. As usual, in many cases the probable source was suspected to be in impure food or drink partaken of in bazaars and villages, when out walking, when out shooting, when travelling by train, when on the march, when attending camps of exercise and manœuvres ; and one medical officer states that even when bazaars are out of bounds, men try to get articles from them secretly. Heat and exertion were also mentioned as contributories. The filth pits were suspected at Ahmednagar, and filth-laden duststorms at Aden and Rawalpindi ; while at Bareilly the dhobi ghats were found to be too near the trenches, and had to be moved. Rawalpindi is considered by the medical officer not to be suitable for the Allahabad system of conservancy. The disease is stated to have been more prevalent than usual among the civil population of Agra ; and at Kirkee the occurrence of seven cases among the native followers was held to have proved that the surrounding population is a danger to the troops ; while suspicious cases were also observed among natives at Quetta and Peshawar. At Allahabad flies were said to be very numerous owing to the operations of the grass farm. Some of the patients attributed their illness to bad smells in the workplace or in the bazaar, to fatigue, exposure to the sun, getting wet. The increase at Jubbulpore was attributed to the arrival of some drafts from England, and at Ranikhet seven out of the 19 men attacked had been not more than nine months in India. At Dagshai the men were suspected of drinking water brought for ablution purposes ; at Lucknow of drinking direct from the taps, instead of using the pinked water. The hospital water at Khandalla was impure, owing to a leaky joint near the kitchen cesspit. The filtering arrangements being on too small a scale, filtered water is supplied to Colaba mixed with unfiltered. The result is that the water is sometimes discoloured and contains an excess of, non-pathogenic, bacteria. At Dinapore the well that has the Pasteur filter installation is said to be secure by its situation, and always to give a good analysis before filtration. The Fatehgarh water contains an excess of chlorides ; and the well in the sapper lines at Roorkee has a large excess of chlorides and hardness, supposed to be due to contamination of the subsoil water in its passage through the polluted soil of the lines and bazaar of the Bengal Sappers and Miners. Some stations are still evilly distinguished by the possession of that dangerous arrangement, a double water-supply. The water-supplies of Madras, Wellington, Rangoon, Mandalay, Schwebo, Meiktila, Poona, Ahmednagar, Mhow, Hyderabad, and Umballa are specially mentioned as being liable to contamination. But at Umballa, Subathu, Dum-Dum, and Barrackpore the water was not considered to have been concerned in the causation of enteric fever. Ten stations report the results of bacteriological examination, which were mostly negative as regards the presence of the enteric bacillus. A microbe having its cultural and tinctorial characters was found in the water bottle of a man who died of the disease at Poona. He was attacked shortly after returning to the cantonment from military training, and admitted having taken water from any source convenient while out in camp. Only in one sample, from No. 3 barrack, was an enteric-like bacillus found at Agra, but it did not react to the serum test. The Chakrata water did not contain any enteric microbes, but the colon bacillus was found in three samples. It has still proved impossible to obtain the respective average annual strengths of abstainers and non-abstainers, so that a legitimate comparison of the incidence of enteric fever on these two classes cannot be made. The nine medical officers who mention the point return 35 abstainers in 162 men attacked, or about 22 per cent. From a few stations it is reported that no system of purification of the water was used or needed. In most stations boiling and the use of potassium permanganate, and sometimes of alum, were continued. From remarks made here and there it appears to be doubtful whether the water always is really boiled ; whether the handling and exposure in the processes of "boiling" and cooling do not in themselves constitute a real danger ; whether the water when ready for drinking is always sufficiently protected ; and how far it is actually used by the men. In the hot weather of the plains, imperfectly cooled water flavoured with permanganate of potassium cannot be a very attractive drink. Considerable efforts seem to be made, in a number of stations at least, to secure the purity of the aërated waters. Most, if not all, soldiers use butter ; but a considerable number use no milk, not even in their tea, and a large number use it only in tea. The subject of dairy management is attracting increased attention, especially with regard to general and detailed cleanliness. Among the most frequently mentioned causes of diminution of enteric fever or immunity from it were the rarity of drafts from England

and the greater age and acclimatization of the men. Additional reasons reported from Bangalore were good water, sanitary improvements, and early diagnosis ; at Rawalpindi inoculation ; at Barrackpore the scrutiny of cases afforded by the use of Widal's test ; at Lucknow the establishment of a government dairy farm in the end of 1899, and a less crowded state of the Barracks ; at Rangoon protection of the wells ; at Jullundur the absence of the young soldiers in the hills ; at Calcutta pure water and great attention to sanitation ; at Nowgong sanitary improvements. Sialkot and Sitapur were immune for the second year in succession. At Rangoon the wells were protected by a concrete barrier all round to a depth of 20 feet ; at Neemuch the chatties were furnished with lids, and long-handled spoons were provided for taking out the water ; at Quetta the eating houses were placed out of bounds, and the troops went into summer camp ; at Agra the latrines of the British infantry lines were treated once a week with corrosive sublimate solution, and those of the Royal Field Artillery with carbolic acid ; at Nowgong the company officers took great interest in the sanitation of the cookhouses and the proper carrying out of the conservancy, and the stools and urine of every patient with diarrhœa and a temperature above normal were disinfected ; at Cherat, Chakrata, and Landour the use of metal vessels for the conveyance of water was introduced ; at Bangalore the stools of even suspicious cases were incinerated. Cooking by European soldier cooks has been started in a good many stations ; but there are certain difficulties connected with the hot weather, and the men themselves do not seem universally pleased with the result. Considerable, and in some cases systematic, use seems to have been made of Widal's test in the diagnosis of cases. As usual, a few anomalous results were recorded ; but, on the other hand, some obscure cases were securely identified as enteric fever. At Rawalpindi and Murree pure cultivations of the bacillus were made from the spleens of patients who had died of the disease. Two cases in hill stations were complicated with diphtheria. In one case at Quetta dysentery supervened after the enteric fever. In a fatal case at Saugor there were two minute abscesses of the liver, and at Jubbulpore a single abscess. Also, in one of the fatal cases returned under abscess of the liver, the hepatic affection was considered to have been possibly due to antecedent enteric fever. Out of the 776 cases of enteric fever which occurred throughout the army of India in 1901, 11 are noticed as having declared themselves among patients in hospital or among attendants. Out of these, 2 were in hospital for early venereal disease, 1 for warts of the penis and tubercle of the lungs, and 6 for other diseases ; and 2 were attendants on enteric fever cases (excluding one man who for more than three weeks before he was attacked had not been in attendance). At Kirkee a man was attacked who had previously suffered from the disease, in 1897 ; and at Quetta one was reinfected while attending hospital after a recent previous attack.

Enteric fever in 1901.—Notwithstanding the resumption of reliefs, there was again a decrease of both morbidity and mortality from enteric fever. Whether the improvement will be maintained after the ordinary system of reliefs has been somewhat longer re-established remains to be seen ; but, so far, the forebodings of last report have not been fulfilled. The number of admissions has steadily declined during the last three years, and it is, of course, possible that a certain amount of the credit may be due to inoculation, as well as to the scarcity of drafts ; but the idea most full of hope is that the reduction may be at least partly due to the work of the special sanitary officers, who, from 1898 onwards, have been engaged in finding out the sanitary defects of stations, especially of stations distinguished by outbreaks or endemic prevalence of enteric fever, and in guiding the authorities to the application of the proper remedies.

The admission rate is the lowest recorded since 1887. There were 776 admissions and 202 deaths, against 970 and 289 in 1900. The average duration of a case was over 55 days, and the average number constantly sick 117·07, which, being multiplied by 365, gives 42,730·55, the total annual loss of service due to sickness only from enteric fever

Enteric fever in the geographical groups.—Groups XIIa, VIII, V, and VI, had, as usual, high decennial ratios of admission ; and Groups II and X, and, to a less extent, I and IV, low ratios. In 1901, though four groups, including VIII and VI, which had the highest admission ratios of the year, showed higher ratios than in 1900, the admission ratios of all groups were below their decennial means. No less than four stations in Group VIII recorded admission ratios over 20 per 1000.

Enteric fever in stations.—Among the stations with strengths over 100 the highest admission ratios of 1901 were those of Nasirabad, Ahmednagar, Bareilly, and Mhow ;

and the highest death-rates those of Murree, Ferozepore, Kasauli, Cherat, and Nasirabad. Fifteen stations registered admission ratios over 20 per 1,000, and of these Neemuch, Nasirabad, Agra, and Mhow were in Group VIII. Five of the eight cases at Neemuch are said to have been contracted elsewhere, and no cause was discovered for the other three. The high rates at Kasauli are not explained. The highest decennial ratios were those of Subathu, Cherat, Taragarh, Dagshai, Benares, Agra, and Lucknow; while low ratios were most common in Burma stations and stations near the sea.

Relation of enteric fever to age and length of residence in India.—In 1901 the greatest liability to suffer and die from enteric fever was between the ages of 20 and 25 and in the first year of Indian service. In 1900 the incidence of the disease had been greater than in 1899 at all age periods except the second, and in all service periods except the first two; but in 1901 it was less than in 1900 in all age periods except the last, and in all service periods except the first. This last fact is probably connected with the arrival in India of about 8,700 men from home during the course of the year, though their arrival fortunately did not prevent the annual ratios of the whole army from falling. In 1901 under one year's service the liability to fall sick of enteric fever was at least twice as great as in any other period of service, and oftener three times or more.

Enteric fever and season.—In the lustrum 1896–1900, so far as can be gathered from the non-calendar returns of the army, the maximum months for India as a whole were April–May and August-September, especially the first month of each of these couples. In the same quinquennium Group XIIa had maxima in April–May and in July-September; Group VIII in April–May and in August–September; Group V in January, March–May, and November–December; Group VI in January, April–June, and November–December. Again, in the same five-year period 10 out of 14 stations had a spring maximum in April–May, and 9 an autumn maximum in July–September; that is, most of them had two maxima; but Dagshai had one long maximum, April-October, and Lucknow three, January, March–April, and November-December. The cold weather maximum appears to be most marked in Northern India, especially in Groups V, VI, VII, and VIII; and may possibly be connected with the more marked changes of season in those regions. A certain influence on the apparent climatic incidence of the disease must be exercised by the usual yearly arrival in October–March of unseasoned men; and it may be noted that in 1900, when there were no arrivals, the curves up to the maxima were not so steep as in the preceding and following years, and the maxima themselves were postponed. Various attempts have been made in this report and elsewhere to explain the regional and seasonal distribution of enteric fever in India, the latest, perhaps, being that of Aldridge; but it must be recognised that, though glimpses of the truth may have been thus attained, a complete explanation is yet to seek. The best authorities are still in doubt as to the relation of enteric fever to season; and Abbott has some justification for saying that the common assumption that enteric fever is mostly an autumnal disease is only correct for sporadic cases in places which do not offer a suitable medium for the development of the enteric bacillus, and that where the conditions are favourable to the bacillus, outbreaks are due entirely to the less or greater pollution of the channels through which the germs can be diffused. Grünbaum has begun investigations as to whether there is any seasonal variation in the bactericidal power of the blood as a possible factor in epidemiology.

Plague and some other general diseases.—In the men of the European army of India there occurred only three cases of plague (two admissions) with one death; one admission at Belgaum and one "on the march," and one death at Ahmedabad. This comparative immunity is no doubt due in part to the great care taken to prevent men coming in contact with the disease, by putting infected areas out of bounds, &c. No officers or children were attacked, and the two women who were admitted, one at Bangalore and one at Bellary (infected at Bangalore), both recovered. It is mentioned that some plague occurred in the native followers of the Royal Field Artillery at Kirkee.

A single case of cerebro-spinal fever, a fatal one, occurred at Mhow. The wide-spread incidence of this disease among natives is mentioned in subsequent sections of the present report. Measles was sometimes contracted from the Boer prisoners. Out of

the 28 cases of beri-beri, 25, with all the three deaths, were returned from Burma, Shwebo and Mandalay having 20 cases between them. The medical officer at Rangoon does not understand how Europeans get the disease, if it is conveyed in rice; but he does not mention whether the soldiers ever drink the native rice liquor. No arsenic was found in the beer supplied to the troops at Mandalay and Meiktila. No cases of dengue were returned.

Tubercle of the lungs.—There was no change in the morbidity, but a fall in the mortality from tubercle of the lungs. For the quinquennium the pulmonary tubercle mortality of the European troops, as well as of the native, was highest in the Bengal Command, that of Bengal being highest for native troops, and that of the Punjab for European in 1901. The mortalities of European troops, of native troops, and of prisoners for the year were as 9, 16, and 75.

Pneumonia and other respiratory diseases.—The admission and the death-rate from pneumonia rose, the former being also higher than the decennial ratio. Burma Inland and the Hills groups had the highest admission ratios, a relation which is not usual, and does not appear to be connected with the distribution of influenza. December was the maximum month, and August the minimum. Khanspur in the Murree hills had the highest admission and death-rates.

With the exception of the Convalescent Depôts, Burma Coast had, as usual, the highest admission ratio for other respiratory diseases. Chaubattia and Campbellpur had the highest hills and plains ratios, respectively; and four other hill stations or depôts and five other plains stations or depôts had admission ratios over 50 per 1000. The high ratio at Umballa was due to the Essex Regiment, which had arrived from Burma, and was under canvas at the beginning of the cold weather.

Dysentery and diarrhœa.—The admission rate from dysentery fell, but the death-rate rose somewhat. Dysentery was, as usual, most prevalent in the Bengal-Orissa group; but it was nevertheless more prevalent, though not so fatal, in the Madras than in the Bengal Command. The maximum period was August-October, and the maximum month September. By far the highest admission and death ratios were those of Barrackpore (304·5 and 28·85); while Dum-Dum had the next highest admission rate (98·8) and Meean Meer the next highest death-rate (11·14). With reference to his former idea that the prevalence of the disease was due to the dampness of the subsoil, the medical officer notes that 1901 was drier than usual. He thinks that the poison is in the barracks or their vicinity, very likely in the latrines and urinals; and that the most important predisposing cause is chill. The men in barracks suffered out of proportion to the married families and staff and departments, and the medical officer asserts that not a single case occurred among the large civil population. One medical officer attending on the cases contracted the disease.

From the conflict of opinion there seems to be emerging the conclusion that in India, as elsewhere, there are two main forms of dysentery; the bacillary, and the amoebic, of which the latter only is apt to be followed by abscess of the liver. Miss Sheldon Amos, however, as the result of a critical review of the literature feels herself forced to the conclusion that no organism has been finally shown to cause any one form of dysentery. The amoebic form as it occurs in Calcutta has been carefully described by L. Rogers. For the benefit of the inexperienced observer it should, however, be noted that recently Shiga, in criticizing the published results of Jaeger, who had reported the existence of amoebic dysentery in East Prussia, calls attention to the fact that the *Amoeba dysenteriae* is not the *Amoeba coli*, and that the finding of the latter in any case proves nothing. The *Amoeba dysenteriae* is from three to five times larger than the *Amoeba coli*, and the boundary between its endoplasm and its ectoplasm is much sharper; its movements and changes of form are much more lively; and it occurs in far greater numbers in the stool. From their great proneness to suppuration of the liver, it would appear that in India Europeans are more liable to amoebic dysentery than natives are; but reason of this, if it is a fact, is not known. E. Pfuhl found the bacillus to remain alive in damp garden earth 101 days; in loose dry sand 12 days; on linen 17 days; in water in the ice-box 9 days, and in water at room temperature 5 days; in Seltzerwater 23 days; in milk 8 to 27 days; in butter 9 days; in Gervais cheese 9 days. Krieger notes that Koch's enteric fever commission are of opinion that the same measures are required against dysentery as against enteric fever.

The admission and death-rates from diarrhœa fell, especially the latter. The admission rates of groups varied between 23·2 in Central India, and 1·0 in Burma Coast. The highest station ratios were at Landour, Meean Meer, and Barrackpore. There was no cholera at any of these stations.

The prevalence of disorders of the digestive system at Umballa was ascribed to drinking on the receipt of bounty money.

Hepatic abscess.—Both the admission and the death-rates from abscess of the liver fell, the former very slightly. The Bengal Command and the Bengal-Orissa group had the highest ratios of admission and mortality. There were 5 deaths at Barrackpore ; and the highest admission and death ratios were those of the same station. Of the 11 cases at Barrackpore, 9 were associated with or sequent on dysentery. In one case each at Neemuch and Kurrachee abscesses of the liver were associated with typhlitis.

As due to abscess of the liver were returned 83 deaths, but to these may be added 18 returned under other heads (dysentery, enteric fever, &c.) in which examination of the body after death showed the presence of abscess of the liver. In these 101 the post-mortem record is complete only for 56, of which 33 were associated with ulceration, and 23 not associated. Three were noted as being associated with dysentery, but without ulceration ; and three as being associated with ulceration, but without dysentery.

Excluding 83 cases in which post-mortem examination was omitted or was incomplete, the total number of fatal cases of which abscess of the liver was found in the 6-year period 1896–1901 was 509. In 271, or 53 per cent., there was found ulceration of the intestine, and in 238, or 47 per cent., no ulceration ; in 171, or 34 per cent., there was a single abscess, and in 338, or 66 per cent., there were more than one.

Among the 271 associated with ulceration, there was a single abscess in 73, or 27 per cent., while there were multiple abscesses in 198, or 73 per cent. On the other hand, when the suppurative hepatitis was unassociated with ulceration there were 98 cases, or 41 per cent., in which the abscess was single, and 140, or 59 per cent., in which the abscesses were multiple.

Again, out of the total of 171 single abscesses, 73, or 43 per cent., were associated with ulceration, and 98, or 57 per cent., not so associated. In contrast to this, among the 338 cases of multiple abscesses, 198, or 59 per cent., were associated, 140, or 41 per cent., unassociated, with intestinal ulceration.

From his experience in Calcutta, L. Rogers finds that the form of bowel disease associated with the large tropical abscess of the liver is amoebic dysentery, though severe sloughing forms of catarrhal dysentery may be associated with small multiple pyaemic abscesses ; that the amoeba is constantly found in an active condition in the wall of tropical abscess of the liver, although frequently absent from the pus in its cavity ; that other organisms are absent from the pus when the abscess is first opened ; and that dysentery or dysenteric lesions are present in at least 90 per cent. of the cases. On the other hand, Manson is somewhat sceptical with regard to both amoebic dysentery and amoebic abscess. Miss Sheldon Amos, in the critical review quoted in last paragraph, does not consider the causative relation of the amoeba to liver abscess as by any means settled.

Venereal diseases.—The admission rate from venereal disease for India was 276·0, against 298·1 in the previous year, and 313·4 in 1899. In other words, in 1901 for every 1,000 men there were about 22 fewer admissions to hospital for venereal disease than in 1900. From the reports of medical officers it appears that some of the principal causes of decrease were believed to be—the greater age and experience of the men, which made them more cautious and more ready to listen to advice ; the working of the cantonment general hospitals ; the interest taken in the matter by regimental and other authorities ; the comparative absence of famine-stricken women ; the more prolonged treatment of constitutional disease ; various measures taken to protect the men ; the out-patient system. Lectures and warnings were frequently addressed to the men by medical officers, chaplains, and regimental officers ; measures were taken to prevent the women being in evidence or soliciting the men ; dangerous places were placed out of bounds ; concerts and other evening amusements were provided.

Alcoholism.—There were 11 deaths from alcoholism, giving a ratio of 0·18, both figures being above those of the two years preceding. The yearly average number of deaths in the decennium 1891–1900 was 7 ; so that the figures of 1901 were considerably above the average. In some cases the receipt of bounty money led to drinking.

Heatstroke.—The heatstroke death-rate for India fell, the decrease being chiefly in Madras, and to a less extent in Bengal. Campbellpur, Delhi, Nowgong, and Deesa had the highest admission ratios, and Meerut and Campbellpur the highest numbers; Deesa and Benares the highest death-rates, and Aden the greatest number of deaths.

Invaliding.—In the whole army of India 2,393 men were invalided, or 39·33 per 1,000 of strength, against 2,026 and 33·46 in the preceding year, the increase being greatly due to the larger number of men invalided for malarial fevers and for debility, and being shared in by all the commands except Madras. The proportion of invalids to strength was lowest in Bengal, and highest, as usual, in Madras. The increase was greatest in the Punjab and Bombay; and in these two commands Ferozepore and Kurrachee, probably on account of the malarial outbreak described in the report for 1900, had most invaliding from ague, Meean Meer and Kirkee from debility. The percentage of men who were invalided while under 25 years of age to the whole number invalided was 42, against 52 in 1900, and of those under 30 years of age 88 per cent., against 90. Of the total number of men invalided, 14 per cent. (against 33) were of less than two years' service, and 60 per cent. (against 72) were of less than 5 years' service. The fall in these percentages in 1900 and again in 1901 is due to the comparative absence of drafts, the army standing fast for most of the time and increasing its age and length of Indian service.

Officers.—The chief causes of admission among officers were ague and simple continued fever; and, while the admission rates from tubercle of the lungs, hepatic abscess, influenza, venereal disease, and simple continued fever rose, those from cholera, small-pox, enteric fever, malarial fevers, and dysentery fell. The chief cause of death was enteric fever, and the ratio was higher than in the previous year. Malarial fevers and abscess of of the liver had also increased ratios. The admissions from influenza, fevers, except ague, diarrhœa, and hepatitic affections were higher than among the men; as were also the death-rates from fevers, circulatory diseases, and hepatic abscess. One officer suffered from a second attack of enteric fever, twenty years after the first. Two officers who suffered from enteric fever at Poona, came from the same bungalow; they had been out shooting and had drunk any water they could get. There was nothing insanitary about the bungalow, but they did not know where their milk came from, or whether it was boiled. The officers' kitchen was found to be insanitary. One officer at Roorkee had been reckless about water and native sweets. At Ahmednagar the disease was thought to have been probably contracted at the mess, as the cook and the mess waiter had both been admitted to hospital for the same disease. One officer at Murree contracted the fever through milk from an insanitary dairy which infected other people in the station.

Women.—The health of the women was decidedly better than in 1900. The chief causes of admission were debility, ague, and the diseases peculiar to women. All the diseases tabulated had lower admission ratios, except influenza, pneumonia, and other respiratory diseases. Debility caused about 39 per cent. of the total admissions, and ague about 17 per cent. The chief cause of death among women was enteric fever, which caused nearly 26 per cent. of the total deaths. Most of the diseases tabulated showed greatly reduced death-rates, but mortality was increased from hepatic abscess, pneumonia, tubercle of the lungs, ague, and enteric fever. As to the causation of the enteric fever, no special remarks are made in the reports.

Children.—There was a great improvement in the health of the children. The chief causes of admission were ague and respiratory diseases. All the diseases tabulated gave diminished admission rates, except whooping cough, cholera, small-pox, enteric fever, and influenza. Ague caused over 23 per cent. of the total sickness, and respiratory diseases nearly 14 per cent. The chief causes of death were diarrhœa and convulsions. Among the causes of death tabulated, only convulsions, cholera, small-pox, and dysentery showed increased mortality. Diarrhœa caused nearly 23 per cent. of the total deaths, and convulsions over 14 per cent. Half the total number of cases of measles occurred at Quetta and Bangalore. Quetta had also the highest number from chicken-pox. In four out of the six cases (five admissions) of tubercle, the intestine, peritonæum, or lymphatic glands were affected; and a fifth was returned as general tuberculosis. The four children who died from tubercle were from two to six years of age. Nothing is said as to the causation of the enteric fever cases.

The liability to death was greatest under six months, the height of the percentage being, as usual, to a considerable degree due to cases of immaturity at birth.

Native Troops.

The health of the native troops was, on the whole, better than in the preceding year, the improvement being in the death-rate. For the population generally the year was one of recovery after famine and epidemic disease.

Year.	Average strength *	Ratio per 1,000 of Strength.							
		Admissions into hospital.	Constantly sick.	Deaths from					Mortality, including absent deaths.
				Cholera.	Remittent Fever.	Pneumonia.	Dysentery.	All causes.	
1896–1900 ...	127,223	781	30	1·03	1·14	3·36	·51	11·81	15·69
1900	123,463	785	30	3·16	1·34	3·32	·63	14·04	18·57
1901	122,800	829	30	0·15	0·12	2·72	·38	10·68	13·89
1891–1900 ...	127,666	852	32	1·11	1·25	3·24	·59	12·22	16·62

* The quinquennial and decennial ratios are, *of course*, worked on the total strength of the lustrum and decade respectively.

The chief cause of admission was ague, and then, with a long interval, came dysentery, venereal disease, and non-pneumonic respiratory disease. Though there were raised admission ratios from influenza, malarial fevers, and respiratory diseases other than pneumonia, there were lessened ratios from cholera, small-pox, enteric fever, bowel complaints, and venereal disease. Ague caused 43 per cent. of the total admissions. The chief causes of death were pneumonia and remittent fever. Among the diseases which caused increased mortality were ague and tubercle of the lungs ; but mortality from cholera, diarrhœa, dysentery, and debility was reduced. Pneumonia caused over 25 per cent. of the total deaths, and intermittent and remittent fevers nearly 21 per cent. The total number invalided for discharge was 1,566 and the chief causes of invaliding were debility, ague, rheumatism, and venereal disease.

The China Expeditionary Force and the China Garrison enjoyed good health, but that of the Ogaden Punitive Force and of the still smaller Ad Dariga Field Force was not so good.

If the following table be compared with that on page 46, it will be seen that the native soldier suffered less from enteric fever, simple continued fever, diarrhœa, hepatitic affections, and venereal diseases ; and more from each of the other causes of admission given than his European comrade. He also suffered more from scurvy. These relations are usual, except with regard to tubercle.

Commands.—Of the commands, Bombay was the most unhealthy, but it was healthier than in 1900. It had the highest mortalities from ague, remittent fever, pneumonia, dysentery, diarrhœa, hepatic abscess, and debility. The highest mortality from cholera and tubercle of the lungs was in Bengal; the highest from enteric fever (on account of the number of Gurkhas) and from non-pneumonic respiratory diseases, and the second highest from pneumonia, in the Punjab; and the highest from small-pox in Madras.

Geographical groups.—The most unhealthy group for the decennium was Assam; but for 1901, the Hills. Burma Coast had the highest admission rate from dysentery and hepatitis, the second highest from venereal disease, and the lowest from ague, non-pneumonic respiratory diseases, and diarrhœa; Burma Inland the highest from ague, simple continued fever, respiratory diseases other than pneumonia, and the lowest from tubercle of the lungs; Assam the highest from enteric fever and abscess of the liver, the lowest from venereal disease, and no pneumonia; Bengal-Orissa the highest from scurvy; Gangetic Plain the highest from cholera and tubercle of the lungs; Deccan the lowest

from dysentery; Western Coast the highest from diarrhœa and venereal disease; Southern India the highest from small-pox and the lowest from remittent fever; the Hills the highest from influenza, remittent fever, and pneumonia, and the second highest from tubercle of the lungs, non-pneumonic respiratory diseases, and scurvy. Scurvy was also high in Indus Valley, and pneumonia in Upper Sub-Himalaya. For the decennium too the highest influenza and remittent fever ratios were in the Hills, the highest enteric fever ratio in Assam, the highest ague ratio in Burma Inland, and the lowest remittent fever ratio in Southern India.

* Including Group Extra India.
† Excluding troops in China and in British East Africa, and including troops in Extra India not in the Indian Command.

Stations, regiments.—The highest death-rates of the large stations throughout India with a strength of not less than 1,000 were those of Bombay, chiefly from pneumonia, plague, dysentery and ague; of Meean Meer, chiefly from pneumonia and remittent fever; of Dera Ismail Khan, chiefly from pneumonia and ague; of Edwardesabad (Bannu), chiefly from pneumonia and remittent fever; of Abbottabad, chiefly from tubercle of the lungs; and of Bakloh, chiefly from tubercle of the lungs and remittent fever. Among the regiments mentioned in the following paragraphs the most unhealthy were the 28th Punjab Infantry, the 21st Madras Pioneers, and the 17th Bengal Infantry on the frontier, the 13th Bombay Infantry at Deesa, the wing of the 12th Burma Infantry at Keng Tung, and the 28th Bombay Pioneers at Kirkee and on the frontier. The two Pioneer regiments were at work on the Khushalgarh-Kohat-Thal Railway. All these regiments suffered from ague, the Madras regiments from simple continued fever in addition, the 28th Bombay Infantry from diarrhœa, and the 28th Punjab Infantry from remittent fever and pneumonia.

Influenza.—The influenza admission ratio was more than ten times greater than in the previous year, though not so high as in 1899. February was the maximum month in 1901, but for the 12 years' period April, with the minimum in October. The highest numbers were at Malakand, Bakloh, Dharmsala, and Benares in India, and among the troops serving in Mauritius. All these outbreaks were compact. The native troops suffered slightly more than the European troops, but much less than the prisoners. The type of the disease appears to have been mild.

Cholera.—There were only 35 cases of cholera with 19 deaths, against 666 cases (641 admissions) with 390 deaths in the preceding year; and the admission and death-rates were, of course, much reduced, and also much below the decennial rates. Cholera reached its maximum in August, and occurred in eight months of the year. The most important outbreak was that of only 12 cases at Fyzabad, of which 11 occurred in the 6th Bengal Infantry and one in the 7th Bengal Lancers. The first man affected in the former had visited the city, where the disease was prevalent, but no exact connexion was discovered; and the man affected in the Lancers had, against orders, visited the infantry lines while the cholera cases were occurring. The three cases in the 1st Bengal Lancers occurred while cholera was prevalent in Lucknow, but no connexion was established between the civil and the military cases, and the possibility of the latter having been really due to ptomaine poisoning is mentioned. There was no cholera in Umballa when the three cases in the 40th Pathans were seen; and it is stated that they were caused by unsound fruit, and that as soon as fruit was forbidden no more cases occurred. But the usual precautions, such as permanganating the water-supply, &c., had been adopted. As to the other regiments affected, the only point mentioned, when anything is said at all, is the presence of the disease in the neigbourhood.

Small-pox.—There were 55 admissions (58 treated) from small-pox with four deaths against 78 (86 treated) with four deaths in the preceding year, and the admission ratio was below the decennial. The highest numbers were nine at Bangalore with two deaths, seven at Bannu without death, six at Quetta with one death, and five at Dera Ismail Khan with one death. The highest regimental number was five in the 4th Sikhs at Bannu. All had good marks of vaccination, and all recovered. The disease came from the bazaar. Two of the men infected in the 2nd Moplahs were pitted from a previous attack; while the third contracted the disease after he had joined the regiment, but before his vaccination had been carried out.

Ague, remittent fever, simple continued fever.—To ague was due over 43 per cent. of the sickness of the native army. Six of the geographical groups had lower ratios, and six higher; but the total increase was greater than the total decrease. The most malarious group was Burma Inland, and it was more malarious than in 1900; but the greatest increase of the ague admission ratio was in Assam. The most malarious month was October, and the least malarious February. The stations with strengths over 100 which had ague ratios higher than 1,000 per 1,000 were, in order, Keng Tung, Kajuri Kach, Deesa, Wana, Bhamo, Rajkot, and Saidgi. The highest admission numbers were recorded in the 21st Madras Pioneers and the 28th Bombay Pioneers, which were employed on railway excavation in malarious valleys on the north-west frontier. The disease in the latter seems to have been of more severe type than in the former. Anopheles mosquitoes were found in the tents, and their larvæ in the neighbouring swamps. The 17th Bengal Infantry was in camp most of the year, in great heat at Suliman Khel, and the men had

to make entrenched camps and build shelters for themselves. No explanation is given with regard to the 13th Bombay Infantry at Deesa. The 28th Punjab Infantry was at Wana, and the anopheles was present, though its breeding places were not discovered. In the report for the Wing of the 12th Burma Infantry at Keng Tung, it is noted that the situation is a lowlying rice-growing valley shut in on all sides by high jungle-covered mountains; that great meteorological variations take place; that the men are badly housed, strange to the place, not careful, and that some had already suffered from fever on the march to Keng Tung.

Remittent fever caused nearly 12 per cent. of the total deaths, and prevailed most in July and least in March, though there was no month that had fewer than 80 admissions. The maximum and minimum of the previous year had been in October and February. The death-rate was high but lowered, the admission rate low but raised. It was most prevalent in the Hills, Bengal-Orissa, and Western Coast. The greatest numbers of cases were at Kila Drosh and Kohat. The 28th Punjab Infantry at Wana and the 10th Madras Infantry at Maymyo had the highest numbers; but in the latter the number had subsided since it left Keng Tung. Next came regiments at Bombay, Almora, Dâtta Khel, and Alipore.

The prophylactic use of quinine does not yet seem to be sufficiently general, sufficiently systematic, early enough begun, or long enough continued.

The 21st Madras Pioneers on the frontier and the 33rd Madras Infantry at Thayetmo had the most cases of simple continued fever. In the report of the latter regiment it is stated that they must be attributed to heat, exposure to the sun, and change of season, and that during the prevalence of simple continued fever there was hardly any case of ague. In the 4th Rajputs at Agra 52 cases were attributed to heat and two to malaria, but the medical officer writing the report is of opinion that probably all were malarial.

Enteric fever, Malta fever.—The admission rate from enteric fever was only half as high as in the preceding year, and the death-rate was also diminished. The ratios for native troops and prisoners are very unlike those for European troops. The statistics do not yet reflect the opinion, so prominent of late, that enteric fever is quite common among natives; and so long as medical officers return few cases, the statistical tables cannot show many. As a matter of fact, in spite of the way in which the attention of medical officers has been called to the possibilities, the number of cases and the ratio were lower than in seven out of the ten years preceding, and below the averages. The years of most enteric fever were 1892, 1897, and 1900. As usual, the total fever mortality of native troops was considerably below that of European troops, as 30 : 49, which seems to indicate that native soldiers really succumb to enteric fever less than their European comrades.

To his 11 cases, mentioned in last report, Lamb has added 10 diagnosed by the serum test, all occurring in Poona in the space of nine months—eight Hindus (six Brahmans), one Parsee, and one native Christian. In Calcutta too, L. Rogers met with 13 cases, diagnosed by the same method, in five months; high class and low class, native Christians, Hindus, and Mussulmans; and one showed marked typical lesions on post mortem examination. A fourteenth case was subsequently tested with a positive result; and then occurred an outbreak of seven cases in a high class Hindu family, children from 5 to 18 years of age, and the blood of the youngest was sent for examination, and gave the reaction. Some regimental cases similarly tested are noticed below. The value of such observations depends, of course, on the trustworthiness of the serum reaction as a test, on the correctness of the technique adopted, and on the competency of those who employ it. The best testimony to the value of the reaction is perhaps the fact that those who use it most have most confidence in it. But it must be conceded that unexpected results are often obtained, some explicable, some not; and that both in Europe and in India experts make mistakes. At the recent meeting of the British Medical Association, Manson related an instance in which he submitted a case of doubtful fever to three experts; one affirmed that the blood gave the reaction of Malta fever, a second declared that it was from a person suffering from typhoid fever, and a third that it was neither of Malta fever nor of typhoid fever. Manson, therefore, asks investigators not to place too great reliance upon serum tests in cases of doubtful forms of illness. Köhler probably goes too far in denying the specific character of the reaction, but his criticisms are calculated to do good by preventing enthusiasts from going too fast. Other cases here and there have been reported among natives of India, not all tested by the serum reaction. The disease is said to be rare in the natives of Egypt and Algeria in the black and red

troops of the United States' army, and in the native and halfcaste soldiers of the French army; and from 40 testings of the blood of Arab children, of which only two were positive (5 per cent.), Brault concludes that no support is lent to the view that adult immunity depends upon a prevalence of the disease in childhood. But the difference of race makes it desirable to have similar observations made independently for India.

In the whole native army of India 26 admissions (27 treated) with 15 deaths were returned, as against 54 (55 treated) with 18 in 1900. Manipur, Abbottabad, and Ferozepore had the highest numbers of cases. To the total 16 regiments contributed, the maximum being six in the 3rd Bengal Infantry at Manipur. The medical officer states that in all the diagnosis was confirmed by the serum test, that the blood of three men who had been in hospital the previous year for "remittent fever" was also found to re-act with the enteric bacillus, and that he has no doubt that mild cases occurred without being detected. In no case was the origin of the disease traced, though in six, water or milk was suspected in a general way. The infection in two cases appeared to have been contracted in hospital, and in one on the march. One of the men affected was a lately joined recruit, and another had only a month's service. In only two of the fatal cases, at Abbottabad, was a postmortem examination obtained, but the result in both confirmed the diagnosis.

There were returned six cases of Malta fever, three from the 40th Pathans, one at Umballa and two at Jhansi, and one each in three other regiments. The medical officer of the 40th Pathans states that the three cases were all diagnostically confirmed at the Kasauli Pasteur Institute by the serum test; and that in addition three or four doubtful cases occurred. In former volumes instances have been cited of the diagnosis of Malta fever in natives of India, and recently that disease has been reported to occur in Assam.

Plague. Cerebrospinal fever.—In 1901 there were 70 cases (69 admissions) of plague with 41 deaths, against 56 with 29 in 1900, 76 with 45 in 1899, and 94 with 58 in 1898. The highest numbers for regiments were 12 in the 15th Madras Infantry at Belgaum and nine in the 1st Madras Lancers at Bellary. The other regiments affected were stationed at Bangalore, Poona, Bombay, Karachi, Ahmedabad, Benares, and in Mauritius, in all of which places the civil population was suffering. In the regiment at Belgaum only three of the cases occurred after the regiment had been reinoculated, some of the men for the third time; and in the regiment at Bellary no inoculated men were attacked. The origin of the two cases which occurred in the 19th Madras Infantry in Mauritius was not apparent, as places where plague prevailed were strictly out of bounds, and no dead rats were found. As the sepoys had been ordered to wear boots at all times, it was interesting to note, says the medical officer, that one of the men affected had the bubo axillary and the other cervical.

Cerebrospinal fever increased from three admissions with two deaths in 1900 to 28 admissions with 21 deaths in 1901. The highest numbers were six in the 8th Bombay Infantry at Delhi, five in the 47th Sikhs at Sialkot, four in the Chitral garrison, and three in the 32nd Pioneers at Jhelum. There were also two at Lucknow, two at Miranshah, and one each at Datta Khel, Jubbulpore, Kamptee, Bannu, Sialkot, and Peshawar. The medical officer of the 5th Madras Infantry at Jubbulpore notes the occurrence of the disease in the Central Prison at that station, and there was a suspicious case of meningitis in the jail at Delhi. In the report on the Chitral garrison the medical officer notes that the disease was epidemic in the lower part of the Chitral valley in the early part of the year, having apparently spread from Asmar, where a similar disease was prevalent, according to bazaar rumour; and that it was also epidemic to the west of Chitral, in Kafiristan, as he had seen some cases in the Utzen valley, and had been told that a large number of persons were dying of the same complaint in the interior. In the pus from the brain and cord of one of the Jhelum cases the Chemical Examiner found the diplococcus. In the 2nd Punjab Infantry overcrowding was considered to be a factor, but there was no overcrowding at Delhi, where the turning over of earth in building operations was supposed to have had possibly something to do with the outbreak. The truth is that the disease is present in the general population.

Tubercle of the lungs.—There was a rise in the admission and death-rates from tubercle of the lungs, all the commands except Madras sharing in the rise. Of groups, Gangetic Plain and Hills had much the highest admission ratios; and of commands, Bengal and Punjab the highest death ratios. Six out of the eight highest admission numbers were in Gurkha regiments, and two in Bengal Lancers. The two highest numbers were in the 2nd Battalion, 5th Gurkhas at Abbottabad, and the 1st Bengal Lancers at

Lucknow. No explanation is given with regard to the first, while the tuberculosis of the second is said to have been the result of service in China, especially in Hong Kong. The medical officer of the 43rd Gurkha Rifles at Shillong, and the medical officer of the 2nd Battalion 2nd Gurkhas seems to agree with him, states that Gurkhas have undoubtedly a special susceptibility partly hereditary and partly acquired, the latter being due to absence of domestic cleanliness. To prevent the men infecting their companions and the barrack rooms, immediate reporting of the cases was insisted on, and the early invaliding of hopeless cases to their homes in Nepal. The medical officer of the 2nd Battalion 2nd Gurkas at Dehra Dun mentions defective ventilation as a factor in causation ; and the medical officer of the 1st Battalion of the same regiment at the same place records lessening of the numbers admitted as probably due to improved ventilation.

As non-tubercular phthisis were returned 13 cases with three deaths. This was only about half the number in the previous year, and it is to be hoped that it will be still further reduced in future.

Pneumonia and other respiratory diseases.—Notwithstanding the increase of influenza, there was a fall in both the admission and the death-rate from pneumonia. In 1901, pneumonia caused over 25 per cent. of the total mortality, and was, as usual, the chief cause of death. The admission ratio is usually greatest in Groups VII and XII ; but in 1901, though Group XII occupied the first place, Group VI came second, and Group VII attained only the fourth place. In all these and for India as a whole pneumonia was most prevalent in the cold months, and especially in December and January. Influenza, on the other hand, was most prevalent in February–April. Admission ratios over 50 per 1,000 appeared among the troops employed on the Mahsud Blockade, and at Sibi, Meean Meer, Wana, and Datta Khel ; and death-rates over 20 per 1,000 at Wana, Kherwara, Sirdarpore, Sarwekai, and Datta Khel. The highest number of cases was in the 40th Pathans at Meean Meer, malarial debility being assigned as the predisposing cause, as it was also in the case of the 3rd Sikhs and the 2nd Punjab Infantry at Datta Khel. No cause could be given for the occurrence of the cases in the 28th Punjab Infantry, but it is noted that the type was septicaemic. The cases in the 21st Punjab Infantry were attributed to exposure on the line of march. The 2nd Punjab Infantry had suffered exposure owing to the Mahsud Blockade operations ; and it is noted that the pneumonia of the Tochi Valley is of a peculiarly virulent kind, and that even the battery mules suffered severely from croupous pneumonia. According to Munson, it is a matter of common knowledge that outbreaks of this disease among soldiers often occur at the same time as epidemics of pneumonia or influenza in cavalry horses with which the men come in constant contact.

Other respiratory diseases were most prevalent in the Punjab Command, and in the Burma Inland and Hills groups. The admission rate was high among the troops employed on the Mahsud Blockade. The stations (leaving out, as usual, those with strengths under 100) with admission ratios over 100 per 1,000 were Datta Khel, Wana, and Jandola ; and with death ratios over 5 per 1,000, Sibi and Datta Khel. The 3rd Sikhs at Datta Khel, a place reported to be exposed to sharp cold wind, had much the highest number of admissions ; and the 28th Punjab Infantry at Wana came next. The medical officer of the 33rd Punjab Infantry at Ferozepore attributes the increase to the dustiness of the season from want of rain, and has always noticed that winter rain and pneumonia vary inversely. It is possible that the causation of pneumonia and bronchitis may not be so distinct as is usually supposed, as Gromakowsky reports that he found the pneumococcus in primary chronic bronchitis almost as often as in pneumonia.

Dysentery and diarrhœa.—The admission and death-rates from dysentery in 1901 were low. All the groups had lowered admission ratios, except Burma Coast, Indus Valley, and Southern India ; and the increase in these three was not very great. The troops employed on the Mahsud Blockade had a very high admission ratio, and a considerable mortality. The only stations of over 100 strength which had admission ratios above 100 per 1,000 were Jandola, Sarwekai, Wana, Kajuri Kach, Datta Khel, and Waziribagh, all on the frontier, all without mortality, except Wana and Waziribagh, in the latter of which it reached 4 per 1,000. The admission ratio was also high in Mauritius, the cases occurring mostly in Port Louis. The 23rd Pioneers at Kharab Kot, &c., and afterwards on the blockade had the highest number of cases, ascribed to chills, errors of diet, and bad water. Next came the 17th Bengal Infantry, which suffered from hard work and exposure at Suliman Khel. Dysentery prevailed more in the second-half of the year than the first, the maximum months being December (Mahsud Blockade) and October (as in 1900).

The diarrhœa admission ratio was reduced, and the mortality much reduced. The greatest prevalence was, as in the previous year, in Western Coast. The highest ratio in Western Coast was that of Bombay ; but the ratios of Sibi, Nowshera, Peshin, Wana, and Kajuri Kach were still higher. The only cause mentioned is for Mir Ali Khel, where the sulphates of sodium and magnesium were present in all the water.

Venereal diseases.—While among European troops an average strength of 60,838 gave 16,789 admissions, in the case of native troops an average strength of 122,806 gave only 4,210 admissions. In other words, there were only 34 admissions for every 1,000 men among native troops, against 276 for every 1,000 among British troops. The admission rate for India was 8·2 per 1,000 of strength less than in 1900 : nearly as much below the ratio of 1900 as that was above the ratio of 1899. There were eight deaths and 128 invalidings directly due to venereal disease. Of the commands, Bombay had the highest ratio ; but all the commands had lowered ratios, and the decrease was greatest in the Hyderabad Contingent and Bombay, which had been affected by the diseased famine women in the previous year. Bombay had the highest ratio, of all the commands, from each form of venereal disease. For India the ratio of each form of disease fell.

Beri-beri.—All the 108 cases of beri-beri (against 146) occurred in Madras regiments, 46 in the peninsular part of the command, 49 in Burma, 11 at Colombo, and one each at Singapore and in Mauritius. The 8th Madras Infantry at Rangoon had the highest number of cases, 48 in two separate outbreaks. The medical officer in a long and careful report attributes these to the consumption by the men of impure rice, water in which such rice was washed or boiled, water contaminated by the preceding, or impure rice liquor. In the sediment of the water out of four wells he discovered raw and boiled starch grains, and was about to recommend the use of permanganate of potash for the wells. That one regiment was infected while another escaped, was considered to be due to the dampness and darkness of the kitchens of the former ; that recruits were specially liable to their want of cleanliness in eating ; that Hindus were attacked in greater proportion than Mussulmans, to the frequent washing by the former of their cookhouse floors with cow dung and water. The channel of infection was believed to have been the alimentary canal ; though the possibility of infection through abrasions of the skin, through the lungs, or by the bites of mosquitoes is discussed, as well as the effect of overcrowding and want of ventilation. The writer of the report was probably influenced by the work of Captain Rost, who believes himself to have proved by experiment that rice and its preparations may convey into the human body a bacillus which is the cause of the disease. Sambon also is of opinion that rice may be a vehicle of a specific infection which lives and works within the patient's body. But there are authorities who are equally convinced that rice has nothing to do with the causation of beri-beri. Of these, Manson is the chief, who at the recent meeting of the British Medical Association explained his well-known views at length, quoting the experiences of Travers, Stanley, and Bolton in support of them. He believes that the immediate cause of beri-beri is a toxin produced by a living germ in some culture medium outside the human body ; and that it does not enter the human body in food or water, but is conveyed to man either by the air or through the skin by contact, or by means of some insect or other animal which inserts it under the skin, or by a combination of some of these ways. Direct infection from man to man also has its advocates ; Ross has brought forward some more instances of the presence of arsenic in the hair of early cases of beri-beri ; while Ashmead believes that the disease is due to carbonic acid poisoning and lack of ventilation. Finally, a view very closely related to one of the modern theories of the causation of scurvy has been enunciated by Uchermann in explaining the results of a Norwegian committee of investigation ; namely, that beri-beri is a multiple neuritis due to a toxin intoxication by tainted vegetable or animal food, the vegetable form corresponding to Asiatic beri-beri, and being usually due to the eating of tainted rice. A suspicion has been expressed, apparently with some justification, that the name beri-beri as used by various observers does not always denote one and the same disease.

Jails of India.

Sickness and Mortality in 1901.—The year 1901 was hotter and slightly drier than usual. The monsoon extended inland very slowly, and retreated unusually early. Actual famine was present only in Gujarat and the Deccan; but many of the prisons were still overcrowded. Like the general population, the prison population improved in health in 1901 as compared with 1900.

The chief causes of admission to hospital were ague, dysentery, abscess, and diarrhœa. Among the diseases with raised admission-rates were ague, influenza, abscess, and respiratory diseases other than pneumonia. Ague caused 38 per cent. of the total sickness, and bowel-complaints 17 per cent. The chief causes of death were dysentery, tubercle of the lungs and pneumonia. Among the diseases with lowered mortality were cholera, diarrhœa, dysentery, debility, remittent fever, and pneumonia. Dysentery and diarrhœa caused 27 per cent. of the total deaths, tubercle of the lungs 14 per cent., and pneumonia 13 per cent.

Cerebrospinal fever continued to increase and spread.

Administrations.—The prisoners of Berar, the Central Provinces, the Andamans, Bengal, and Burma, had better health than in the previous year; and the difference was considerable in the case of Berar and the Central Provinces. The most unhealthy administrations were, in order, the Andamans, Bombay, and Bengal; and the three most healthy in order, Burma, Berar, and Madras. Of the former group, Bombay and the Andamans were worse than in the quinquennium. As compared both with the previous year and with the quinquennium, the year 1901 had increase of mortality in the Andamans from tubercle of the lungs and dysentery; in Assam from anæmia and debility; in Bengal from small-pox; in the United Provinces from cholera, tubercle of the lungs, and respiratory diseases other than pneumonia; in the Punjab from dysentery and debility; in Bombay from tubercle of the lungs, pneumonia, and other respiratory diseases; in Berar from remittent fever; in the Central Provinces from non-pneumonic respiratory diseases; and in Madras from tubercle of the lungs. Thus four provinces, just mentioned, had increased mortality from tubercle of the lungs.

Andamans.—The rainfall was more than 49 inches greater than in the previous year, and more than 24 inches over the lustral average. The convict population has been steadily increasing for at least the last five years. The constantly sick and death-rates have decreased during the last three years, but not to anything like the same extent as the corresponding ratios of the troops and police than which they were in 1901 very much higher. Though for the Andamans some of the features are satisfactory (such as the reduction in remittent fever mortality), the crying fact remains that the mortalities from tubercle of the lungs and from dysentery, always an opprobrium of the Settlement, are still increasing. The list of vegetables supplied is very poor in such as are of antiscorbutic value; but the number of admissions from scurvy, though three times greater than in the two preceding years, was not high in proportion to strength. Possibly, however, improvement in the antiscorbutics might lessen the mortality from dysentery. As usual, fever was specially prevalent in the rainy season, the great increase in admissions to hospital coinciding with some very stormy and wet weather which occurred in June and July. There was a great epidemic of malarial fever in the female jail, in which the disease was characterized by its resistance to large doses of quinine, and by the occurrence of three or four relapses of four or five days' duration at intervals of ten to fourteen days, crescents being often very numerous in the blood. Mosquito nets were found more efficacious than quinine. The medical officer, noting the extreme frequency with which intestinal ulceration is met with in fatal cases of phthisis, considers it possible that in some cases the intestinal tuberculosis may precede the pulmonary, and may be grafted on repeated attacks of dysentery. Such a possibility calls for all the more energy in the efforts made to prevent dysentery. That disease was in several instances contracted in hospital from patients suffering therefrom. Measures were accordingly taken for the isolation of the sick, for the destruction of their excreta, and for the supply of boiled water to all prisoners, however far their work might take them from the main supply. These measures were only introduced late in the year, but are said to have been already attended by a considerable amount of success. The sputum and alvine discharges of phthisical patients are also now burnt, as well as the dysenteric stools, in the incinerators; and plans and estimates for a large ward for the isolation of phthisis cases have been called for, and a site chosen. It was time for such measures, as it has been shown above that mortality from tubercle of the lungs and from dysentery

Prisoners.

* The quinquennial and decennial ratios are, of course, worked on the total strength of the lustrum and decade respectively.

† Excluding subsidiary jails.

‡ Including Ajmer, Quetta, and Mercara.

(*a*) Excluding jails transferred to North-West Frontier Province.

was higher than the quinquennial average and higher than in 1900. Epidemics of mumps and of influenza occurred.

Burma.—The information afforded by the Inspector-General as to the health of his prisoners is extremely meagre. Overcrowding to a slight extent took place in the jails at Prome, Henzada, and Myanaung; but was quickly relieved by transfers to other jails. As in the previous year, the health of the prisoners was very good, and the death-rate was the lowest on record. But the scurvy admission-rate was higher than in any other province, and the cholera mortality was lower only than that of Madras. An epidemic of 20 cases of cholera with 12 deaths in the Insein Central Prison was referred to infected tobacco introduced by a prisoner sent in from a police lock-up without any intimation that he had for some time been in intimate contact with cholera cases. The origin of the four cases in the Paungdi jail was not traced, but cases were occurring within three furlongs of the jail. The admission-rate of Burma for tubercle of the lungs was above that of India. Of the convicts admitted into jail, over 14 per cent. confessed to the habitual use of opium.

Assam.—Though the ratios were somewhat higher than in the preceding year the health of the Assam prisoners, like that of the general population, was, on the whole, good. There was diminished mortality from pneumonia, dysentery, and cholera; and increased mortality from diarrhœa and remittent fever. Very little useful information, outside of tables, is to be obtained from the administration report. The origin of the single case of cholera, in the Cachar jail, was not traced. Assam had the highest mortality ratios from malarial fevers and from debility, and high mortality ratios from dysentery and diarrhœa; but it had no mortality from tubercle of the lungs, and the lowest admission ratio from the same.

Bengal.—The health of the Bengal prisoners improved, as did that of the general population. All the ratios given are favourable in 1901, except that the smallpox mortality ratio was higher than that of the preceding year and quinquennium and the dysentery ratio higher than that for the lustrum. Overcrowding could "usually" be obviated by the use of temporary buildings and factories (an unsatisfactory device), or by transfer of prisoners, and building operations are in progress which will add largely to the jail accommodation. The Berhampore jail has been connected with the municipal water-supply, and the Midnapur jail is also getting a pipe-supply; but the eight Pasteur-Chamberland filters in the jails of the province are reported to be very liable to get out of order, and not to have proved a great success. Influenza was present in a number of the jails. At Bankipore the first prisoner attacked by cholera was a convict on outdoor labour; at Monghyr the first two cases were those of prisoners working outside who were believed to have got contaminated milk from a passer-by; and at Muzaffarpur and Hooghly the origin of the disease could not be traced. The results of the treatment of dysentery by izal were on the whole not encouraging. The dysentery of the Midnapur Central and Barisal jails was connected, in the opinion of the Inspector-General, with a deficient supply of fresh vegetables. Plague occurred in three jails, the most at Bankipore. Most of the cases of cerebrospinal fever appeared in the Bhagalpur Central Prison, but six other jails returned the disease. It is noteworthy of itself and in connexion with what was said under the head of the Andamans, that in four of the fatal cases of "dysentery" at Hooghly advanced tubercle of the lungs was found. In the Alipore Central Prison the prevalence of tubercle of the lungs was attributed to overcrowding and defective ventilation, and the measures taken in consequence are considered to have already met with some success. Modern scientific arrangements have been made in some jails for the treatment of the tuberculous sick and the protection of others.

United Provinces.—Though the year was described as healthy, and the health of the general population as good with a slightly diminished mortality, the health of the prisoners was not so good as in the previous year. There was greater mortality from tubercle of the lungs, dysentery, and heatstroke; and there were fatal epidemics of cholera and cerebrospinal fever. Transfers on account of overcrowding were not so frequently necessary as in 1900. Efforts were made, as far as funds permitted, to improve the water-supply in the jails; and the supplies of the Lucknow and Benares Central and of the Jaunpur and Moradabad District jails are mentioned as requiring attention. The Benares District Jail is being connected with the municipal water-supply, but is not considered likely ever to be a healthy jail. Influenza was present in many of the jails; and cerebrospinal fever in five, that most severely affected being the Allahabad District Jail. Except in the Lucknow jails, cholera was successfully stamped out after

the occurrence of a single case. The outbreak at Lucknow appeared to be part of a general epidemic which affected the city, the cantonments, and all the villages round the jails most severely, long before a case appeared in the jails. No proof of the introduction of the disease by flies or in any other way was obtained. One result of the prisoners having to be in cholera camp in the rains was a high mortality from dysentery. The requisite accommodation for the isolation of dysentery patients was not always at hand, but increased attention was given to the destruction of their evacuations. The Inspector-General believes that "dysentery" is in many cases merely a terminal symptom of malarial cachexia and not due to specific dysenteric infection. But it would not be safe to act upon that belief, especially as it is quite as likely that a malarial cachectic may be an unusually easy prey to a dysenteric infection. A special ward for the treatment of tubercle of the lungs was erected in a large open space in the Agra Central Prison, and it is intended to provide similar wards in other jails. Meanwhile, open-air treatment and isolation are adopted whenever possible.

Punjab.—In the Punjab also the standard of health of the prisoners was lower than even in the previous year, though the health of the general population was, on the whole, improved. It may be noted, however, that seven out of the ten district jails with highest mortality were in districts stated by the Sanitary Commissioner to have had high mortality among the general population. Other explanations attempted by medical officers from purely local points of view were, with right, not considered satisfactory by the Inspector-General. The mortality ratios from tubercle of the lungs, pneumonia, and dysentery, though improved, were still high, while that from diarrhœa was higher than before. There was a good deal of pressure on the accommodation, but crowding was avoided by pitching tents outside the jail walls as far as practicable. Four jails have already received, and two more are about to receive, a piped water-supply. The distribution by hand in other jails is a danger to the purity of the otherwise generally satisfactory drinking water. During the year efforts were made to improve the personal hygiene of the prisoners, and the Allahabad system of filth disposal was introduced into most jails with success. In addition to the quinine prophylaxis of malaria, special attention was given to drainage and the disposal of spill-water, and steps were taken to fill up excavations in the neighbourhood of jails; but in these respects much remains to be done. In 13 jails there was no mortality from dysentery, but on the whole it caused a high mortality; and the Inspector-General rightly emphasizes the necessity for carefully detailed measures based on the belief that the disease is infectious. He considers also that one of the chief causes of pneumonia in jails is the habit of wrapping the head in the bedding during sleep. A special isolation ward in the Lahore Central Prison was sanctioned for the treatment of tuberculous patients; and elsewhere modern treatment was adopted as far as practicable. There was an outbreak of cerebro-spinal fever in the Mung Rasul Central Prison.

North West Frontier Province.—The jails of Peshawar, Kohat, Bannu, Dera Ismail Khan, and Abbottabad did not come under the administration of the new province till the 9th of November, 1901; but for convenience it was ordered that they should be taken as in that province the whole year; and for the same reason the quinquennial figures are given in the table. There was a considerable increase of mortality. Some of this was due to heatstroke, not always inside the jails; but there was also comparatively high mortality from smallpox, pneumonia, and dysentery. There was no cholera and no mortality from tubercle of the lungs. The chief cause of sickness was malaria, against which prophylactics were issued in the autumnal months.

Bombay.—Though the sick ratios increased, the prisoners of Bombay had, like the free population, a considerably reduced mortality. Famine was present only in Gujarat and the Deccan. Among the prisoners there was a substantially lowered mortality from bowel-complaints, but increased mortality from tubercle of the lungs and from respiratory diseases, especially pneumonia. All the jails except three were overcrowded, and work-sheds and tents had to be used. The latter, when pitched outside the jail, are far preferable. Eight out of twelve overcrowded jails had a mortality over 33 per 1,000, and the tubercle in the House of Correction was suspected to be due to the overcrowding. Wherever necessary, special issues of food, clothing, and fever prophylactic medicine were made. There was no cholera. In the Bombay Common jail, nine deaths took place from relapsing fever, a disease which also occurs in the city outside the jail. One death from cerebro-spinal fever was returned in September from the Ahmedabad Central Prison.* Cases of

* An outbreak followed in February, March, and April, 1902; and the free population was also said to be affected at that time.

plague occurred in five jails. There was much sickness and mortality from pneumonia in the Sind Gang and a good deal in the Ahmedabad Central Prison; and the Bombay administration had the highest pneumonia mortality ratio.

Berar.—The general population of Berar is described as having been unusually healthy and free from epidemic disease, the aged and weakly having succumbed to the late famine. The health of the prisoners also greatly improved, and might "be described as normal." But tubercle of the lungs and pneumonia mortalities were still above their lustral ratios. An epidemic of influenza occurred in the Amraoti Central Prison. In Akola ankylostomiasis used to be mistaken for scurvy; and since the true nature of the disease was recognised, sickness and mortality from it have been diminished.

Central Provinces.—The population of the Central Provinces was healthier than in the preceding year, and the ratios for the prisoners were much improved, especially those of mortality. There were no deaths from cholera, small-pox, or remittent fever; and the ratios of death from tubercle of the lungs, pneumonia, dysentery, diarrhœa, and debility were reduced. But the Central Provinces was the administration that had the highest death-rate from diarrhœa, the mortality from respiratory diseases other than pneumonia was higher than in 1900, and cerebrospinal fever occurred in two jails. There was not so much difficulty as in the foregoing year about overcrowding. It is stated, however, that four jails had generally more prisoners than sleeping barracks were meant to contain; but that the excess was satisfactorily housed in the worksheds at night; and that extramural camps were not necessary to relieve overcrowding. This use of worksheds cannot be called satisfactory from a sanitary point of view. The Punjab rule is a sound one that excess prisoners must be placed in tents outside the jail, unless special permission is obtained to treat them otherwise. The Jubbulpore Central Prison, with low admission and constantly sick rates, had high mortality, chiefly from bowel-complaints. The frequent occurrence of gangrenous dysentery in this jail has not been satisfactorily explained, and the matter is under investigation. Special inquiry should be made as to the nature, quality, issue, and cooking of the food.

Madras.—Though the prisoners of Madras had higher ratios of sickness than in the previous year, their mortality was, like that of the general population, lower. There was greater mortality from cholera and tubercule of the lungs, but less from pneumonia and dysentery. Six jails were overcrowded, the excess being accommodated in workshops and temporary sheds, or removed by transfer. The use of workshops for the purpose is objectionable (See under Central Provinces); and temporary buildings should not be erected within the jail enclosure wall, unless there is legitimate space for them. Cholera appeared in three central and five district jails; and evacuation, partial or complete, was in every case attended with the best results. In the case of the Vellore Central Prison the disease was restricted to a batch of new arrivals, and the great value of extramural quarantine was proved. The exact manner of introduction into jails was not traced in any case, though flies, rise of subsoil water, and disturbance of cholera-burial-ground soil are mentioned in connexion with causation. The first case at Berhampore occurred in a man who had attended the Sessions Court four days before. The Berhampore water had been pronounced suspicious, and was boiled before use. The prisoners continued to use the jail water after going into camp, a very risky thing to do; but no more cases occurred. An attempt, not very clear, is made by the medical officer to explain why there were so many cases of malarial fever in the Rajamundry Central Prison in 1901, but he does not explain why there were so many more than in the preceding year. Dysentery was also prevalent in the same jail, and was not stopped by antimalarial prophylaxis or by permanganating the water; and the treatment by izal was not found very satisfactory. The Trichinopoly Central Prison returned not only 30 admissions and 6 deaths from tubercle of the lungs, but also 40 admissions and 16 deaths from tubercle of the intestines. This seems to call for serious investigation. The Inspector-General doubts the diagnosis in at least some of the cases; and the medical officer gives no special explanation, though he mentions that his jail might be called a convalescent depôt, and recommends the provision of a special tubercule ward. In 1900 the same jail returned 19 cases of tubercle of the intestines.

Coorg. Rajputana. Baluchistan.—The Mercara jail was much less healthy than in the previous year, the death-rate being more than three times as great. No less than nine deaths from diarrhœa and three from debility took place in this small jail. No explanation is given. The Ajmer jail was much more healthy than in the preceding year of famine, there being a great reduction in dysentery mortality, and the ratios in general approaching more nearly to the normal of the quinquennium. The Quetta statistics were less favourable than in 1900.

The General Population.

Census of 1901.—The third general census of India was taken on the night of the 1st of March, 1901. The populations of the whole Empire were enumerated, except those inhabiting West Manglün, the trans-Salween Northern Shan States, and certain tracts of the Baluchistan Agency. Although the area of the operations was nearly sixteen hundred thousand square miles, and the number enumerated close upon three hundred millions, the preliminary results were declared within a fortnight. A result of this triumph of organisation is the use in the provincial Sanitary Reports for 1901 of the new census figures.

The total population enumerated was 293,475,477, an increase of 6,079,483 or 2·1 per cent. over the population of 1891. But 2,293,629 of the increase is due to the inclusion of territories not included in 1891, so that the actual increase during the ten years of the populations enumerated in that year was 3,785,854, or 1·3 per cent. In the following table the facts are set forth in detail.

British Provinces and Native States.		Population (1901).	Population (1891)	Increase or decrease (+ or −).		Population of area not included in 1891 census.	Increase excluding area not included in 1891 census.

* Including the Civil and Military Station of Bangalore.

Alterations in the numbers of the populations. Relation to rainfall.—In seven of the British provinces there was an increase of the population ranging from 21·2 per cent. in Lower Burma and 7·6 per cent. in the Panjab (including the North-West Frontier Province), to 1·6 per cent. in the United Provinces. In the remaining four British provinces the populations declined at rates varying between 1·7 per cent. in Bombay and 12·0 per cent. in Ajmer-Merwara.

The changes in the numbers of the population in different parts of the country during the last ten years furnish a striking illustration of the close dependence of the Indian peoples upon a sufficient and normally distributed rainfall.

The monsoon rainfall was in serious defect (—4·76″) over the whole of northern and central India in 1895, and in the following year the defect over the same areas was even greater (—5·33″). In 1899, although the monsoon rains were unusually heavy in Assam, Bengal, and Bihar, they completely failed (—11·14″) over north-western and western India and the Deccan. In several years also the autumn and cold weather rains were deficient.

If a map showing the parts of the country where the population has increased and decreased is examined, it will be found that the areas in which the most serious decrease occurred may be enclosed in an irregular quadrilateral described by lines joining the following points; the north-west corner of Cutch, the extreme north of Rajputana, the south-east of the Central Provinces and the south of the district of Belgaum. This figure includes, particularly in the south, areas in which there has been an increase in population, while it excludes areas where there was a decrease; but the increase in the included areas may depend in some cases on the rainfall not having been seriously deficient, while the decrease in the excluded areas seems to be due in many cases to an excess of rain rather than to a deficiency. Nearly the whole of the quadrilateral depends for its main supply of rain on the south-west monsoon current from the Arabian Sea, although parts in the north of the figure receive rain from the Bay current.

The southern border of the area of decreased population follows more or less closely a line to the south of which the autumn rainfall is normally over five inches. Taking the total rainfall of the decennium, the amount discharged by the south west monsoon was in defect in the greater part of Bombay, Rajputana, Central India, the Central Provinces, the north and east of Madras, Eastern Bengal, Assam and Upper Burma; while the discharge from the north-east monsoon was in defect in much the same areas, and also in Sind and Lower Burma.

The ten years may be divided into two periods; the first from April, 1891, to March, 1895, when the rainfall over a great part of the country was in excess; the second from April, 1895, to March, 1901, when the rainfall was in great defect. The area in which there was a great excess in the first period corresponds fairly closely with the area in which there was a great deficiency in the second period; but in both periods there was a deficiency over the coast districts of Bombay, in the north and west of Madras, in part of Eastern Bengal, Assam and Upper Burma; and in both periods there was excess in the extreme north-west of the Panjab, in certain northern and south-eastern districts of the United Provinces, in the north-western districts of Bengal and in deltaic Burma.

But the effects of epidemics on the population must not be overlooked. The relationship between cholera prevalence and rainfall is a complex one, and probably varies in different parts of the country and at different seasons of the year. Among several severe cholera years, the decennium includes three in which the mortality recorded was unprecedented. In 1891 the number of deaths recorded from cholera in the British provinces was 581,409, in the following year the number rose to 724,348, and in 1900 it was 809,179. The aggregate number of deaths recorded in the ten years was 4,505,019, of which 1,970,833 were registered in Bengal, 814,659 in the United Provinces, 619,956 in Madras and 391,430 in Bombay—in the case of the last named a number greater than the decrease in the population during the decennium. A new cause of mortality was also at work, for although the number of deaths registered as due to plague up to the end of 1900 was a little less than a fourteenth of the number ascribed to cholera during the decennium, the disease had obtained a firm hold in only a few of the provinces. In Bombay the number of recorded deaths from plague, from 1896 to 1900, was 265,912, only 3,437 less than the number recorded as due to cholera in the same period, which includes 1900, a year of unparallelled cholera mortality in Bombay.

In the vast area of an Indian province the conditions of race, climate and environment vary so much that it would be surprising if the results obtained in particular districts were always in conformity with those obtained in the province generally.

In most provinces in which the population increased, there were districts where it diminished, and in most provinces where the population diminished there were districts where it increased. In Madras the population increased in every district; but in Coorg the population of the district of Padinalknad decreased.

In Bengal the populations of seven districts decreased. In Patna, Gaya and Saran the main cause of the decrease was mortality from plague, but in the cases of Gaya and Saran the census operations were partially disorganised by the presence of plague, so that there is some uncertainty about the actual numbers of the people. Champarun and Shahabad suffered severely in the lean years and were very unhealthy; while the districts of Purnea and Jessore were unhealthy throughout the decennium. In every one of those districts except Jessore the rainfall in both periods of the decennium was in excess. In Jessore the rainfall in the second period was in excess.

In Assam the populations of two districts declined; Nowgong, where *kala azar* was very severe, and emigration increased while immigration decreased; and Kamrup, where, in spite of the gradual disappearance of *kala azar*, the public health was bad and there was a good deal of emigration.

In the United Provinces no less than 18 districts shew a falling off in population, the amount varying between 11·5 per cent. in Azamgarh and ·3 per cent. in Rai Bareli. Most of these districts are in the south and east of the province, and the recorded deaths exceeded in number the recorded births in most of them in 1891, 1894 and 1897, and in some of them in 1895 and 1896. Here we have to do with the effects not only of drought in certain seasons but of too much rain in others, for the mortality in the districts in the Eastern plain and in the Eastern and Western Sub-Himalayan tracts is stated to have been due to diseases induced by excessive rain, which probably did more damage to the crops in these districts than drought.

In the Punjab the population declined in seven districts, Montgomery in the south and the six districts which run continuously along the north of the province from Umballa in the east to Jhelum in the west. The cause of the decrease in Umballa is obscure, but appears to have been general "unhealthiness." In the cases of the other districts the people emigrated to more favoured parts of the country.

In the Central Provinces most districts suffered severely from famine and the effects of famine, but the fall in the numbers of the population was aided by the emigration of between 150,000 and 200,000 people. mostly to the tea districts of Assam, but partly also to Berar, where prior to 1900, conditions were more favourable to agriculture than in the Central Provinces. In three districts the population increased. Sumbalpur, in the east of the province, depends for rain upon the current from the Bay of Bengal and suffered but little from drought; Nimar, which increased by 14·4 per cent., received immigrants from Khandesh, Berar and the adjoining native territory. Chhindwara, where the increase was very small, received emigrants from the *jagirs*.

In Berar the population of Akola increased. There was immigration into the district, but the actual increase is among the female population and is attributed to their more accurate enumeration.

In Bombay, the population of the province of Sind increased by 11·7 per cent., and in the districts of Ratnagiri, Dharwar, Kanara, and Kolaba the populations increased. In Sind, agriculture depends upon irrigation, and plague was less prevalent than in the Presidency. The districts of Ratnagiri and Kolaba supply the labour market of the capital, and the increase in their populations may be due to exodus from the latter.

Results of registration.—The following table (*see* page 80) exhibits the excess or defect of the populations determined by the census of 1901 as compared with the same populations in 1891, and also shews the results of registration.

A word of explanation regarding the figures in the table is necessary. While the areas under registration are always included in the areas of the census operations, the areas do not generally quite coincide. The population for which vital statistics are registered is in most cases slightly less than the population enumerated at the census. The figures in columns 2 and 3 are, therefore, not comparable, but the percentages in columns 4 and 5 are comparable. In the figures representing the results of registration no account is taken of emigration or immigration; *e.g.*, Assam receives large numbers of emigrants from the United Provinces and the Central Provinces; and from these and from other provinces, there is a considerable flow of emigration to places out of India.

It will be observed that in Madras and Bombay the results of registration appear to agree very closely with the results of the census; but this appearance of agreement is misleading. In Madras both the birth-rates and death-rates are very low, and both are very much lower in the country than in the towns; while if the district figures are examined separately, it will be found that the registration and census figures do not agree. Thus, in the presidency town the registration figures shew a decrease of the population of 1·2 per cent., while the census shews an increase of 12·6 per cent. In twelve of the districts the census totals are higher than the registration totals, the excess ranging from 0·1 per cent. of the population in Kurnool, to 5·7 per cent. in Godavari and 9·6 per cent. in the Nilgiris. In 10 districts the excess of births over deaths is higher than the census totals, the difference varying between 0·1 per cent. in Salem and 4·9 in Nellore.

In Bombay the agreement between census and registration results disappears when the figures for the Presidency proper and Sind are taken separately. In Bombay the census shews a decline of 4·10 per cent. and registration a decline of 2·03, while in Sind the population has increased by 11·68 per cent., although the increase shewn by the registration figures is only 2·88 per cent.

Registration, 1891–1900.—The following paragraphs contain a brief analysis of the figures registered during the 10 years ending with 1900.

Birth-rates.—Making allowance for a rise in the population in most provinces, and for a fall in a few, and for the effects of famine and plague, a study of the birth-rates recorded in the nine years ending with 1900 seems to shew that registration is improving slowly but surely. The range between the highest birth-rate recorded, 50·5 per 1,000 in Berar in 1899, and the lowest, 14·67 in Ajmer-Merwara in 1900, is very wide, rates are consistently low in Madras (extremes 25·1—31·8) and Coorg (16·15—26·62), and do not shew much signs of improving, and rates in Bombay (26·87—36·76) under the stress of accumulated misfortunes are declining; but in Burma the rise in the rates has been almost continuously progressive from 24·83 per 1,000 in 1892 to 38·37 in 1900; and in Bengal (extremes 28·15—42·96), Assam (28·59—35·45), the United Provinces (31·10—48·09) and the Panjab (34·02—48·4), the rates tend to be higher towards the

end of the period. In the Central Provinces (26·85—47·35) the low rates recorded between 1895 and 1898, inclusive, and in Berar (31·3—50·5) the low rates of 1898 and 1900, are due to the years of famine.

The highest rate recorded in 1891 was 43·09 in the Central Provinces; in 1892 the highest rate was 39·9 in Berar; in 1893, the highest rate was 40·95 in the United Provinces. In all other years, save 1899,—a year of high rates, when 50·5 was registered in Berar, 48·4 in the Punjab, 48·09 in the United Provinces and 42·96 in Bengal—the Punjab headed the list, the rates varying between 43·9 in 1894, and 41·0 in 1898.

Proportion of the sexes at birth.—The provincial figures showing the proportions of the sexes at birth present remarkable features, and would be of great interest if it was possible to discriminate between the peculiarities due to race and environment and the peculiarities due to imperfect and wrong registration.

During the fifty years ending with 1900, the highest percentage of male to female births recorded in England and Wales in any year was 105·2 in 1857, and the lowest 103·2 in 1898, so that the variation between the extremes was only 2 per cent. If, however, separate counties are taken, the variation is much greater. In 1900 the highest percentage was 112 recorded in Westmoreland, and the lowest 96·1 in Herefordshire; and both these figures indicate a considerable departure from the average, which for the 10 years ending 1899 was 101·4 in Westmoreland, and 102·9 in Herefordshire.*

The Indian provinces, with two exceptions, shew far higher percentages than England and Wales, and some of them shew greater variations from year to year than the English counties, but the figures registered in each province are generally fairly characteristic.

The provinces may be grouped in four divisions. Those in which the percentages were low, the average for the 10 years ending 1900 being below 105; those in which the percentages were moderate, average between 106 and 108; those in which they were high, average 108 to 110; and those in which the percentages were extremely high, above 115.

To the first division belong only two provinces, Coorg (average 101·2) and Madras (104·4). To the second belong six, Bombay, excluding Sind (106·2), the Central Provinces (106·4), Bengal (106·5), Berar (106·6), Lower Burma (107·4) and Assam (107·6). High percentages were recorded in the United Provinces (108·9) and the Punjab, excluding the Peshawar and Derajat Divisions (110); and extremely high percentages in Ajmer-Merwara (116·8), the Peshawar and Derajat Divisions (121·9) and Sind (124·3).

That unduly high percentages of male to female births are the result of wrong classification rather than omission to register is evidenced by the fact that these percentages have gradually declined in the different provinces out of proportion to the rise in the birth-rates. There seems, however, to be good reason to believe that as we recede from the sea into dry climates where the variations of temperature are extreme, the proportions of male to female births increase.

The variations between the highest and lowest percentages registered during the 10 years are of interest.

Here again the provinces may be placed in four groups; where the variation was very small, Bombay (·8 per cent.) and Madras (·9); where the variation was small, Berar (2·1), the Central Provinces (2·47), Assam (2·87), Bengal (3·0) and Burma (3·0); where the variation was considerable, Sind (3·4), the Punjab (4), the United Provinces (4·46); and where the variation was very great, Coorg (11·54), Peshawar and Derajat Divisions (12·3) and Ajmer-Merwara (19·46).

It may be remarked that the population of Coorg is only 180,401; and that in three of the ten years the percentage of male to female births was below 100, the lowest being 95·80, registered in 1899. The extreme variation in Ajmer-Merwara seems to be due to bad registration. The constancy of the high percentage recorded in Sind is certainly remarkable.

Death-rates.—Excepting the United Provinces, Madras and the Punjab, the highest mortality in every province recorded during the 10 years ending with 1900 occurred in one of two years, 1897 and 1900. In the former year the highest death-rates were

* Annual Report of the Registrar General, 1900, page liii & lx.

registered in Assam (50·61), the Central Provinces (69·34), Madras (25·4) and Coorg (50·03); while exceptionally high rates were registered in the United Provinces, Berar and Bombay. In 1900 the greatest mortality was recorded in Bengal (36·63), Berar (82·7), Bombay (70·07), Ajmer-Merwara (119·97) and Lower Burma (27·51); while high rates were registered in the Punjab, the Central Provinces and Coorg. In the United Provinces the highest rate was 42·51, registered in 1894, when cholera was very severe and fevers unusually deadly. In the Punjab the high rate recorded in 1900 follows closely the maximum (49·48) recorded in 1892, when there was the severest epidemic of cholera since 1867, and fevers, including a wide-spread epidemic of influenza, were extraordinarily fatal. In Assam (29·91), Coorg (21·79), Ajmer-Merwara (20·23) and Lower Burma (15·93) the lowest death-rates were registered in 1891. In Coorg the census of 1891 showed that there had been a material decrease in the population, so that the rate in that year was computed on too large a population. In Lower Burma the rates have increased fairly steadily from year to year. In all the other provinces the minima were recorded in 1893 or 1898. In the former year the lowest rates were returned from the United Provinces (24·10), the Punjab (28·13), Madras (19·3) and Bombay (27·20); in the latter from the adjoining provinces of Bengal (26·57), the Central Provinces (24·30) and Berar (23·4).

Death-rates of sexes at different ages.—The following table shows, but, unfortunately, not with complete accuracy, the average death-rates at each age period among the two sexes in the British provinces.

Mean ratio of deaths during 1891–1900.

* Mean of nine years.

With regard to every province it will be observed that in infancy the male death-rate is the higher. In the age period 1-5 the male death-rate is the higher in all provinces except the Punjab. In the following age period Bombay is a second exception to the general rule. Between 10-15, females in the Punjab, Bombay, Berar and Coorg died at a greater rate than males; while in Madras males and females died at the same rate. In the age period 15–20, which represents early married life, females died at the higher rate in every province except in Bengal and the Central Provinces, and in Lower Burma, where marriage is later than in India. In the age period 20–30 the female death-rates were the higher everywhere, except in Bengal and the Central Provinces. Between the ages of 30 and 40 the female rates were the higher in Lower Burma and the Punjab alone, and after the age of 40 males died at the greater rate everywhere, except in the Punjab, where, after the age of 60, females died at the greater rate.

Mortality curves.—By using the figures in the table it is easy to make curves representing the average mortality among the two sexes in the different provinces during the ten years ending with 1900, and it is instructive to compare such curves with those representing English mortality.

Mortality in England and Wales, 1841–1850 *and* 1886–1895.—If curves exhibiting the mortality of males and females in England and Wales during the 10 years ending with 1850 are constructed, it will be found that the lines descend rapidly to the point represented by the age period 5–10, and from thence gradually to 10–15, whence there is a very gradual ascent to the age period 25–35, after which the ascent is more rapid, becoming steep after 45. Curves representing the mortality in England and Wales in the decennium ending 1895 retain the same general shape as those of the earlier decade, descending rapidly to the age period 5–10, gradually to a minimum in the age period 10–15, and then ascending slowly to 35, when the lines, especially that representing the mortality of males, ascend steeply. But in the curves of the later decennium the age period 5–10 is at a lower level, and the slope to 10–15 is more gradual ; the lower level is retained in the case of males to between 35 and 45, and in the case of females to the age of 55. There is another very important difference. Sixty years ago, female mortality was greater than male mortality between the ages of 10 and 20, and again between the ages of 25 and 35. In the 10 years ending with 1895, female mortality was greater than male mortality only between the ages of 10 and 15 ; the mortality of the sexes was equal between the ages of 15 and 20, after which females died at a much lower rate than males. The striking difference between the curves of the two decades is, then, the greatly lower level of the curves of the later period representing an enormous saving of life of children and adults up to early middle life, and especially of adolescent females and young married women.

Indian Provinces, 1891–1900.—If, now, the curves representing the average mortality in all Indian provinces during the 10 years ending with 1900 are examined, the contrast is very striking. There is the same rapid fall in early life to the age period 5–10, when there is generally another rapid fall to the age period 10–15, the lowest point in the male curve of every province, and in the female curve in every province except Assam and Coorg, in both of which the minimum occurs at the age period 5–10. From 15 the ascent begins, always less gradual than in the English curves, the lines representing male deaths rising steeply between 30 and 40, the lines representing female deaths between 40 and 50.

No Indian curve descends so low as even the 1841–50 English curves, and most Indian curves shew in a marked degree the interlacing of the lines representing male and female deaths which we have seen was a feature of the earlier English curves. In some provinces the charts are peculiar. The Madras curves are on a lower level and are more gradual than any of the others. The lines representing mortality in Coorg rise after 15 almost as rapidly as they descend to 15. The lines representing male deaths in Bengal and the Central Provinces are always higher than the lines representing female deaths, although at the ages between 15 and 20 the latter nearly approaches the former. On the other hand, the line representing female mortality in the Punjab is higher than the line representing male mortality, except in infancy and late middle age. The Bombay chart resembles that of the Punjab.

The Assam chart presents a remarkable feature. There is a very sharp rise about the age of 20 in the line representing males. A similar rise of the male curve appears in the charts of Bengal and the Central Provinces, but not so markedly as in the case of Assam. In most provinces there is a rise of the female curve at this age, and in all, except Bengal and the Central Provinces, the curve of female mortality rises above the curve of male mortality at the child-bearing period.

A study of the English charts shews the saving of life at the most enjoyable and useful ages which improvement in the environment has effected ; and a comparison of the Indian chart suggests that analogous improvements might effect enormous saving of life in India, particularly the lives of children and of young adults, and especially of women at the child-bearing age.

Mortality from chief diseases, 1891–1900.—Let us now analyse the figures registered regarding deaths caused by the principal diseases in the various provinces.

Cholera death-rates.—Cholera was the cause of deaths in every province in every year of the decennium, except in Ajmer-Merwara in 1894 and 1899, in Coorg in 1895, 1899 and 1900, and in the Punjab, the Central Provinces and Berar in 1898. The lowest death-rates recorded in the other provinces were ·91 in Bengal, ·05 in the United Provinces, and ·23 in Bombay, all in 1898 ; ·6 in Madras in 1895 and ·52 in Lower Burma in 1891. The lowest cholera death-rate recorded in Assam was 1·66, which, it may be noted, is much higher than the minimum recorded in any other province. Six

times in the ten years the highest provincial death-rate from cholera was recorded in Assam ; twice, in 1892 and 1900, in Ajmer-Merwara ; and once each in the United Provinces, in 1894, and the Central Provinces, 1896. The highest death-rates recorded during the ten years were 8·93 in Ajmer-Merwara and 8·71 in Bombay, both in 1900.

Cholera, sex mortality.—In Bengal, Madras and Lower Burma males suffered more than females in every year of the ten. In the remaining provinces the male rates were either higher than, or equal with the female rates, except in Assam where the female rates were the higher in five years, and the United Provinces where they were the higher in four years.

Cholera mortality, town and country.—Speaking generally, the rates were higher in the towns than in the country, but it was only in Bengal and Madras that this was invariably the case ; while in Bombay and the United Provinces the rates were higher in the country than in the towns, in eight years in the case of Bombay, and in six years in the case of the United Provinces.

Small-pox death-rates.—The small-pox death-rates varied greatly, between 7·05 per 1,000 recorded in Ajmer-Merwara in 1896, and ·01 recorded in Berar in 1891. From 1891 to 1893 the highest rates were recorded in Coorg. In five of the remaining seven years the highest rates were recorded in Ajmer-Merwara, Assam sharing the distinction in 1894, and the United Provinces and Lower Burma furnishing the highest rates in 1897 and 1898, respectively.

The lowest rates were registered once in Coorg, four times in Berar, and five times in the United Provinces. In 1895 the distinction was shared with the United Provinces by Coorg, and in 1897 the rate in Bombay was the same as that recorded in Berar.

Small-pox, sex mortality.—In most provinces, particularly Lower Burma, Bengal and the Central Provinces, males suffered more than females ; but in the Punjab the female death rates were higher than the male in six years, and equal with them in two years. In Ajmer-Merwara the female rates were higher than the male in seven years. In Berar and Madras, where the small-pox death rates were always low, the death-rates of the sexes were generally equal.

Small-pox mortality, town and country.—In Bombay and the Punjab the town populations suffered more than the country people, but in Lower Burma, Madras, Coorg and the United Provinces the rural populations suffered more than the urban.

Fever death-rates.—Under the heading fevers are included the deaths due to a large number of different diseases, and it is not possible in the present condition of registration to say what proportion in each province of the fever death-rate is due to malaria. Some of the provincial fever death-rates, however, maintain the same characters year after year. In Madras, where the death-rate from fever was lowest in every year of the decennium—except 1891, the rates varied from 9·0 to 7·3 per 1000, while in the little province of Coorg, embedded in Madras, they ranged from 41·50 to 15·61. In Lower Burma the rates were always low, fluctuating between 11·90 in 1898, and 7·76 in 1891.

In Berar the rates were generally low, but the range from the exceptional rate of 29·5 registered in 1900, to 11·5 in 1898, was considerable. In Assam the rates were uniform but on a somewhat higher level, varying between 28·74 in 1897 and 14·70 in 1900. In Bombay the lowest rate was 12·14, registered in 1899, and the highest rate, 28·87, was registered in the following year. In Bengal there was little variation in the rates, the maximum being 25·32 and the minimum 18·94 ; but in the Central Provinces the range was extreme, from 16·17 in 1899 to 40·98 in 1897. In the United Provinces the rates fluctuated between 18·84 and 31·88 ; and in the Punjab between 18·57 and 34·83. In Ajmer-Merwara the rates varied greatly, from 13·05 in 1891 to 81·56 in 1900.

Fever, sex mortality.—In every province, save the Punjab, Coorg, Ajmer-Merwara and Bombay, males invariably suffered more than females. In Bombay they suffered more in eight years, and in Ajmer-Merwara in six years. In Coorg, however, females are reported to have died at the greater rate in six of the ten years, and in the Punjab the female death-rate was invariably the higher.

Fever mortality, town and country.—In Bengal, the Punjab, the Central Provinces, and Coorg, the rural populations always suffered more than the urban populations, and they generally suffered more in the other provinces, except in the United Provinces, where in nine of the ten years the highest death-rates were registered among the towns' populations.

Dysentery and diarrhœa death-rates.—The recorded provincial death-rates from dysentery and diarrhœa display some remarkable peculiarities. In Bengal the rates were always low and fluctuated only slightly from ·91 to ·52 per 1,000, while in the neighbouring province of Assam the rates were uniformly high, varying between 4·61 and 2·74. In Madras the rates varied between 1·2 and ·7, whereas in Coorg the range was from 3·11 to ·64. In the United Provinces (1·41 to ·50), the Punjab (1·26 to ·59) and Lower Burma (1·95 to ·91), the variations were inconsiderable, but in Ajmer-Merwara the rates ranged from ·70 in 1896 to 15·90 in 1900. In 1900 enormous death-rates were registered also in Bombay, 11·59, and Berar, 22·4. In these provinces the rates in other years ranged in Bombay from 1·75 in 1893 to 4·57 in 1897, and in Berar, where the rates were always high, from 3·5 in 1898 to 10·3 in 1897. The Central Provinces also suffered excessively in 1900, when the rate was 5·16, and in 1897 when it was 8·53; the minimum for the 10 years in the Central Provinces, 1·23, being recorded in 1898.

Dysentery and diarrhœa sex mortality.—In every province, except Madras and Berar, in every year, males suffered more than females. In Madras the death-rates of the sexes were equal in 1895. In Berar the rates were equal in 1892 and 1899, and in 1891 the female rate was slightly the higher.

Dysentery and diarrhœa mortality, town and country.—In all provinces, except Bombay and Berar, the towns' populations suffered most. In Bombay in 1891 the rural death-rate was considerably the higher, and in Berar in every year, except in the famine years 1897 and 1900, the rural population suffered most.

All other causes.—It might be expected that the death-rates under the heading "all other causes" would be higher in the towns than in the rural areas, and, except in Berar in 1900, this was invaribly the case. The urban and rural maxima were registered in 1900 in every province except Assam, where the maxima were registered in 1897, and the United Provinces, where the maxima were registered in 1899. In Madras and Ajmer-Merwara although the highest urban rates were recorded in 1900, the highest rural rates were recorded in 1891 and 1894, respectively.

Before proceeding to the consideration of the statistics registered in the various provinces in 1901, the following figures relating to the populations claim attention.

Sex and age constitution of the populations.—The sex and age distribution of the people in the British provinces is shewn in the following table, in which is given the sex composition in 1891 and the sex and age and composition in 1901 of each thousand persons in each province.

Age and Sex Constitution of Provincial Populations.

* Fractions are omitted, but it should be noted that in the Central Provinces the male population is slightly the greater.
† The details of the figures for Burma are not available.

It will be observed that in 1891 in India there were 509 males to every 491 females, and that in 1901 the proportion of females had slightly increased, the figures being 508 males to 492 females. In 1891 there was an excess of males in every province except two, the excess being most marked in Coorg, the Punjab, and Ajmer-Merwara. In the Central Provinces the numbers of the sexes were nearly equal, and in Madras and Bengal there was a slight excess of females.

In 1901, the excess of females in Madras has increased, and there is now an excess of females in the Central Provinces; but in the vast population of Bengal the small excess of females has become a small excess of males, which is to be set off against the fact that in each of the remaining provinces, except Coorg, the excess of males has slightly diminished.

Birth-rates in 1901.—In 1901 the average birth-rate throughout the British provinces of India was 34·7 as compared with 36·6 in the preceding year, ranging from 41·35 per 1,000 of the population in the United Provinces to 16·10 in Ajmer-Merwara.

Birth-rates computed on the number of females in the populations.—It is sometimes urged in extenuation of the registration of a very low birth-rate that there is a deficiency of females in the population, so that it is of interest to compare the birth-rates obtained when the births recorded are computed upon the female populations between the ages of 15 and 40. This has been done in the table below.

Province.	Population of females, 15-40 years.	Total births, 1901 (males and females).	Birth-rate during 1901 (per 1,000 of females 15-40 years).	Arranged in Order.			
				Province.	Birth-rate (1901) per 1,000 of total population.	Province.	Birth-rate (1901) per 1,000 of females 15-40 years.
Bengal	14,948,435	2,870,806	192·0	United Provinces of Agra and Oudh.	41·35	United Provinces of Agra and Oudh.	214·3
Assam	1,081,618	179,289	163·8	Bengal	38·57	Bengal	192·0

Bombay Presidency	3,638,657	465.647	128·0	Coorg	18·83	Coorg	94·8
Ajmer-Merwara	104,873	7,679	73·2	Ajmer-Merwara	16·10	Ajmer-Merwara	73·2
Total	42,965,005	7,571,128		Total	16·10	Total	176·2

For facility of comparison the provinces have been arranged in two columns, in the first in order of descending birth-rates computed upon the numbers of the total populations, in the second in the order of descending birth-rates computed upon the numbers of females between the ages of 15 and 40.

It will be observed that both lists begin with the United Provinces, Bengal, the Punjab, and Assam, and both end with Coorg and Ajmer-Merwara. With rates computed on the total population, the North-West Frontier Province comes below Berar, and Madras below Bombay, but with rates computed on the number of females the positions are reversed.

Proportion of sexes at death, 1901.—In every thousand persons whose deaths were registered in India in 1901, there were 521 males and 479 females. In the United Provinces and Bombay the proportions of the sexes dying were the same as the average for all India. In Berar, the Punjab, and Madras, the excess of male deaths was less than the average. In the remaining provinces the excess of male deaths was greater than the average, considerably in Bengal, Assam, Ajmer-Merwara, and the Central Provinces, greatly in the North-West Frontier Province.

The following table gives the details, and also shows the age and sex composition of each thousand deaths in India and in each of the British provinces.

Age and Sex of each 1,000 *Persons who Died in each Province during* 1901.

In every province more males died than females, and in every province, except the Punjab and the North-West Frontier Province, the male death-rate was the higher. Under ordinary circumstances, males die at a greater rate than females at all ages except those at which reproduction takes place.

Fallacy of crude death-rates.—It is evident, then, that other things being equal, the higher the proportion of males in a population the higher the death-rate will be. But children, particularly infants, and aged persons die at a greater rate than persons in the prime of life; so that the more infants and old people in a population the higher the death-rate will be, apart altogether from conditions specially affecting health; although, of course, the more unfavourable the conditions, the more will children and old people suffer. A glance at the table on page 84 will show how different are the age and sex constitutions of the different Indian Provinces. As instances, there are 18 male infants in the North-West Frontier Province for every 7 in Ajmer-Merwara, while there are 33 old men in the Punjab for every 13 in Coorg. As in India generally, in 1901 the death-rate of male infants was 253·0 and of old men 77·4 among every thousand, it is obvious that death-rates computed without reference to the age constitution of the populations fail as an index of salubrity or the reverse, and that some method of correction is necessary. Where there is no difficulty in estimating the population from year to year and registration is accurate, such a correction is easily made; but in India where the gradual increase of the populations is checked by famine and rendered irregular by the occurrence of great epidemics, the difficulty is very great, while the value of the correction is reduced by the fact that deficiencies in registration may and do cause a greater difference in the actual total than the correction.

Attempt to correct death-rates.—In the following table an attempt is made to correct the provincial death-rates;—

Province.	Standard death-rate.	Factor for correction for sex and age distribution.	Recorded death-rate for 1901.	Corrected death-rate for 1901.	Comparative mortality figure, 1901.
(1)	(2)	(3)	(4)	(5)	(6)
India	29·6	1·00	29·6	29·6	1,000
Bengal	29·5	1·00	31·04	31·04	1,049
Assam	30·5	·97	27·85	27·01	912
United Provinces of Agra and Oudh ...	30·0	·99	30·30	30·00	1,014
Punjab	30·7	·96	36·13	34·68	1,172
North-West Frontier Province	31·2	·95	19·16	18·20	615
Central Provinces	27·4	1·08	23·46	25·34	856
Berar	26·6	1·11	27·6	30·64	1,035
Madras Presidency	30·0	·99	21·3	21·09	712
Coorg	27·6	1·07	36·49	39·04	1,319
Bombay Presidency	27·4	1·08	37·12	40·09	1,354
Ajmer-Merwara	23·8	1·24	33·13	41·08	1,388

Method used for correction.—Column 2.—The standard death-rate is obtained in the following way.* The population of all India as determined by the census of 1901 is divided into two groups, males and females. Each group is then subdivided by age-periods into ten sub-groups.† The numbers of deaths registered in 1901‡ in each sub-group are then used to calculate the death-rate per 1,000 of that sub-group. In the case of each province the popoulation is divided by sex and age periods into similar sub groups. Against each sub-group the death-rate recorded in the corresponding sub-group in the population of all India is placed, and the number of deaths corresponding to that death-rate is assumed to have taken place in the sub-group. From the aggregate number of assumed deaths in the sub-groups a death-rate per 1,000 of the actual population of the province is calculated.

Thus the standard death-rate for all India is the recorded death-rate, while the standard death-rate for a province is that which would be registered if the mortality in the province among the two sexes at different ages was exactly the same as in all India.

Column 3.—The factor for correction is obtained by dividing the standard Indian death-rate by the provincial standard death-rate.

Column 4.—Contains the death rate recorded in 1901.

Column 5.—The corrected death-rate is obtained by multiplying the recorded death-rate by the factor for correction.

Column 6.—The comparative mortality figures correspond to the corrected death-rates. The death-rate for India being taken as 1,000, the provincial death-rates are brought to the proportional whole number.

* The methods will be found fully described in Dr. Newsholme's "Elements of Vital Statistics," 3rd Edition, page 109. *Cf.* Dr. Ogle's letter to the Registrar General in the supplement to his forty-fifth Annual Report.

† Age periods 0-1, 1-5, 5-10, 10-15, 15-20, 20-30, 30-40, 40-50, 50-60, 60 and upwards.

‡ A ten years' average is out of the question.

If the provinces are arranged in two columns according to the recorded death-rates and the corrected death-rates, it will be noticed that, except in the case of Ajmer-Merwara, no important change results in the relative position of the Provinces. The comparative mortality figures are, however, interesting.

The following statement furnishes a brief epitome of the birth and death statistics recorded in the different provinces in 1900 and 1901 :—

Birth and Death Statistics.

* Excluding Zamindaries. † Not available ‡ Statistics for 13 towns.

Bengal.—The rainfall in Bengal in 1901 was scanty and unevenly distributed, the south-west monsoon began late and ceased early, and the October rainfall was in defect everywhere except in Eastern Bengal. Unfavourable meteorological conditions affected the outturn of food grains which was below the average in many districts. The number of births recorded during the year was 2,870,806, or 121,224 more than in 1900. The birth-rate was 38·57, or 1·63 per 1,000 higher than that of the preceding year calculated upon the same population, while it was 1·83 per 1,000 higher than the quinquennial average computed on the census figure of 1891. It would appear then that registration is improving, but that much remains to be done is evident from the great divergence in the birth-rates of the different districts, from 19 of which, headed by Muzaffarpur (44·69), Dinajpur (44·41), and Patna (44·06), rates in excess of 40 per 1,000 were returned, while in four—Puri (29·57), Hooghly (27·99), 24-Parganas (27·70), and Calcutta (10·76)—the rates were below 30 per 1,000. In only ten towns were birth-rates recorded in excess of 40 per 1,000, and, generally speaking, the birth-rates in towns were much lower than the birth-rates in the adjoining country. The causes of this are explained to be the large floating population and the deficiency of females in the towns, and the custom of sending townswomen to be delivered in the country. It might be added that registration is less defective in the country than in the towns. The average percentage number of male to female births was 105, but the variations, though not extreme, were considerable, from 111 in the 24-Parganas and 110 in Calcutta and Hooghly where the lowest provincial birth-rates were registered, and 110 in Purnea, to 101 in Palamau.

The total number of deaths recorded was 2,310,424, or 293,312 fewer than in 1900. The death-rate was 31·04 per 1,000 of the population, and ·19 per 1,000 higher than the quinquennial average calculated upon the smaller population of the 1891 census. By far the highest district death-rate was 56·79, registered in Patna, only two others were over 40 per 1,000, Gaya (45·68), and Puri (41·32). The three lowest death-rates were 20·21, 20·70, and 20·88, in the Sonthal Parganas, Ranchi, and Singhbum, respectively. The average urban death-rate was 37·12, or 6·40 per 1,000 more than in the country, the excess being mainly due to diseases registered under the heading "other causes." Deaths ascribed to fevers were, however, far more numerous in the country than in the towns, while to dysentery and diarrhœa were ascribed a far larger number of deaths in the towns than in the country.

These results are in accordance with what we might expect. Where there is no scarcity, dysentery and diarrhœa are far more dangerous to children in crowded areas than in the open country, while precision of diagnosis tends to raise the proportion of deaths registered under "other causes."

The variation in the actual rates recorded in the different towns was enormous, due in cases, where the rates were excessive, to the occurrence of epidemic disease, and when the rates were very low to bad registration and to deficient numbers of females.

The mortality among infants was 189·56 among males and 171·96 among females, per 1,000 born. Children between one year and five years of age died at the rates of 44·87 and 39·15 per 1,000 boys and girls living at that age.

At all ages the male death rates were higher than the female, the averages being 32·64 per 1,000 for males and 29·44 for females.

Hindus died at the rate of 32·12 per 1,000 and Muhammadans at the rate of 30·06; other classes and Budhists at the rates of 21·73 and 21·58; and Christians at the rate of 16·69.

Port of Calcutta.—The number of European seamen estimated to have arrived in the port of Calcutta was 19,630, or 1,813 less than in 1900, but the daily average number in the port was 1,150 against 989. Only 19 deaths occurred, yielding a death rate of 16·52 per 1,000 as compared with 51 deaths and a death rate of 51·56 in the previous year. The average daily native population of the port was 25,630. Only 137 deaths were reported among them, equal to a death rate of 5·34 per 1,000 against 9·40 per 1,000 in 1900.

Assam.—In Assam registration is carried out in the Surma and Brahmaputra valleys and in parts of certain hill districts, viz., the Khasi and Jaintia Hills, the Garo Hills and the Naga Hills, but the general provincial statistics refer to the Surma and Brahmaputra valleys only. In 1901, the number of births recorded was 179,289 as compared with 184,427 in the preceding year. The birth rate in 1901 was 33·98. The populations of the two valleys are approximately equal in number, but registration is apparently on the

whole better in the Surma than in the Brahmaputra valley, for in only one district of the latter, Goalpara, are the figures obtained in accordance with the probable facts. The highest district birth rate was 44·25 per 1,000 in Goalpara, followed by 36·49 and 35·38 in Sylhet and Cachar, respectively. In three districts, Nowgong (29·84), Sibsagar (26·34), and Lakhimpur (26·28) the rates were lower than 30 per 1,000. In the towns the average birth rate was 29·82 per 1,000, ranging from 47·71 in Barpeta and 36·57 in Nowgong, to 20·20 in Silchar and 12·88 in Tezpur. It is explained that a considerable number of births registered as taking place in Barpeta occur in extra-municipal areas, the population of which is not reckoned in that of the town ; while of Tezpur it is said that registration is more defective than in any other town. The average percentage of male to female births was 107·97, varying between 104·45 in Goalpara and 111·88 in Sibsagar.

The number of deaths registered was 146,939, or 14,692 fewer than in 1900, yielding a death rate of 27·85 per 1,000. Among the districts the highest death rates were recorded in Darrang (35·19), Goalpara (34·09) and Cachar (29·96), and the lowest in Lakhimpur (24·11), Kamrup (23·04) and Sibsagar (21·71). The urban death rate was 29·74, or 1·93 higher than the rural, and ranged from 54·26 in Golaghat and 42·72 in North Lakhimpur, in both of which fevers and bowel complaints caused excessive death rates, to 14·11 in Maulvi Bazar. In the province generally, the lowest mortality occurred in February, and the highest in May. In the Surma Valley the minimum mortality was recorded in October and the maximum in December, while in the Brahmaputra Valley the fewest deaths were recorded in February and the most in July.

The recorded mortality among male infants was 195·4 and among female infants 195·8 per 1,000 born, respectively. In the age periods 15–20 and 20–30, the female mortality was higher than the male, the averages for all age periods being 28·51 among males and 27·16 among females.

Immigration.—There has been a great decline in the numbers of immigrants during the last five years. In 1897 the total number was 95,931, in 1898 the number fell to 49,169, and in 1899 to 31,908. In 1900 there was famine in the recruiting districts and the number of immigrants rose to 62,733, but in 1901 it fell to 26,233. The cause of the falling-off in the number of immigrants is ascribed to the depressed state of the tea industry and to the more stringent provisions of the new Labour Act. There has been a very satisfactory decrease in the mortality among the coolies in transit. In the Brahmaputra Valley the number of deaths during transit, including deaths at the depôts in 1901, was 69, including 48 from cholera, against 594, including 528 from cholera in 1900. The Assam-Bengal Railway is now being largely used for the conveyance of coolies in the Surma Valley. There were only two deaths in this area, both at river depôts.

United Provinces of Agra and Oudh.—The number of births recorded in the United Provinces was 1,972,131, or about 80,000 more than in 1900, yielding a birth rate of 41·35 per 1,000. In 11 of the districts, headed by Hardoi (51·28), Moradabad (50·13) and Budaun (49·93), the birth rates were more than 45 per 1,000, and in only two districts, Dehra Dun (27·81) and Azamgarh (28·94), were they lower than 30 per 1,000. The average birth rate in the towns was 40·28, the highest rates being 57·90, 55·54 and 54·51 in Pihani, Rae Bareli and Bilsi, respectively. In Naini Tal (18·08) and Mussoorie (16·67) the birth rates were below 20 per 1,000. The percentage of male and female births ranged from 113·61 in Muzaffarnagar, to 101·92 in Garhwal, the provincial average being 107·73.

The death rate was 30·30 per 1,000 of the population, the number of deaths recorded having been 1,445,035, or about 15,000 fewer than in 1900. The highest district death-rates were recorded in Benares (40·35) where plague occurred, Farrukhabad (39·84), where the "fever" death rate was very high and cholera was present, and Hardoi (38·69), where 5·33 per 1,000 of the population died of cholera. In 21 districts, including all those in the Fyzabad and Gorakhpur Divisions, the death rates were below 30 per 1,000, the lowest being 21·10, 20·89 and 19·69 recorded in Azamgarh, Almora and Gorakhpur respectively. In the town of Sahatwar in Ballia the death-rate of 110·90 was registered, including rates of 63·52 under the heading "fevers," and 28·93 from cholera. In Brindaban, where cholera was severe (6·82), and fevers extraordinarily so (66·29), the death-rate was 76·11 ; and in Benares, where plague was prevalent, it was 74·66. In 12 others of the larger towns the rates were over 50, and in only 15 were they lower than 30 per 1,000, the average urban death-rate being 42·87, as compared with 29·34 in the

rural circles. The monthly death-rate, which was 1·99 in January, fell in February to 1 69, and then rose fairly steadily until October, when the maximum, 3·62 was reached, after which the death-rate fell to 3·30 in December.

The death-rates of Christians and 'Other Classes' were computed at 8·82 and 17·35 per 1,000, respectively, but the figures in certain of the districts are obviously not correct. Muhammadans died at the rate of 28·81, and Hindus, who constitute more than five-sixths of the population, at the rate of 30·65.

The death-rate of male infants was 237·33 and of female infants 227·83 per 1000 born, respectively. Boys and girls between the ages of one year and five years died at the rates of 54·12 and 54·50 per thousand living as determined by the recent census. At all other age-periods, save 15-20 and 20-30, the male were higher than the female death-rates, the averages being 30·59 for males and 29·99 for females.

Punjab.—The exceptionally unhealthy autumn of 1900 resulted in a considerable decline in the birth-rate in the Punjab and only 712,553 births were registered, equal to a birth-rate of 35·4 per thousand of the population. In only three districts Sialkot (44·1), Gurgaon (40·6) and Gujranwala (40·1) were the rates over 40 per 1000, while in four, Umballa (29·1), Montgomery (28·5), Ferozepore (28·2) and Simla (15·8) they were under 30. In the district of Jhang alone, was the birth-rate in excess of the quinquennial mean, and in twelve districts the births were exceeded in number by the deaths. The provincial percentage of male to female births was 110·1, the percentage ranging from 119·9 in Dera Ghazi Khan to 106 in Ludhiana.

The recorded deaths numbered 726,611 against 980,211 in 1900, and the death-rate was 36·1 per thousand. In several of the districts, notably Ludhiana (52·2), Karnal (51·5) and Ferozepore (48·8) excessively high rates were registered. Ludhiana and Ferozepore were among the ten districts in which plague occurred, but in nether of them was the death-rate attributed to plague high ; in both districts, however, as well as in Karnal the fever and "all other causes" death-rates were high, which in the cases of Ludhiana and Ferozepore is suggestive of the faulty registration of plague, or of the occurrence of some other very fatal epidemic disease. The urban death-rate was 37·71. or 1·75 per 1000 higher than the rural death-rate. Enormous death-rates were registered in many of the towns, Rahon, where to plague and "other causes" death-rates of 8·55 and 49·48 respectively, were ascribed, heading the list with a death-rate of 90·97 per thousand, Zaffarwal, a small town in the Sialkot district, followed with 89·09 per thousand, including 36·47 from plague. The next highest death-rate was 88·38 recorded in Kila Sobha Sing, also a small town in Sialkot where the significant death-rate of 60·22 was registered as due to fevers, and only 8·39 as due to plague.

The death-rates among the various sects shewed considerable variation, 15·57 among Christians and 44·62 among 'Other Classes' being the extremes; Hindus and Muhammadans died at the rates of 39·14 and 33·58, respectively.

The spring and summer were the healthiest seasons ; the maximum mortality was reached in November 5·10 and December 5·08.

The death-rates among infants were 296 and 260 per 1000 males and females born, respectively. At all age-periods except 40—50 and 50—60, the female death-rates were the higher, the averages being 34·5 for male and 38·1 for females. In every district, except Jhelum, the female death-rate in 1901 was higher than the male, but the differences were not great in the districts of the Rawal Pindi Division, where, as also in Mianwali, Gurgaon and Rohtak, the quinquennial mean death-rates of males were either slightly higher than, or about the same as, the death-rates of females.

North-West Frontier Province.—In the North-West Frontier Province, which comprises the districts of Hazara, Peshawar, Kohat, Bunnu and Dera Ismail Khan, the number of births recorded in 1901 was 60,413 as compared with 62,084 in the preceding year. The birth-rate was 29·5, ranging in the districts from 33·6 in Kohat to 24·7 in Peshawar. The registered percentage of male to female births was 123·2, the district figures varying between the extraordinary one of 138·7 in Peshawar, and the high one of 111·1 in Hazara.

Deaths numbered 39,208 against 52,103 in 1900. The provincial death-rate was 19·2, varying between 25·6 in Dera Ismail Khan and 16·6 in Hazara. The urban death-rate was 18·28, or ·98 per thousand lower than in the rural areas, and ranged from 30·63 in Nawashahr to 13·11 in Kohat and 4·17 in Abbottabad. The Hindu death-rate was 17·44 as compared with 19·53 among Muhammadans.

The lowest death-rates 1.34 occurred in the months of April and September, and the highest 2·06 and 2·05 in November and December, respectively. The death-rate among male infants was 174·48 and among female infants 163·00, per 1,000 born, respectively. At all age-periods, except 1·5 and 50-60, the female death-rates were the higher.

Central Provinces.—Only 279,998, births were recorded in the Central Provinces, including the zamindaries, against 313,116 in 1900, and the birth-rate in 1901 was 28·83, a lower rate than any recorded during the last 20 years, except in 1897, when the rate was 26·83 per thousand. In only four districts, Nimar (37·22), Burhanpur (35·45), Chhindwara (35·35) and Mandla (35·05), were the birth-rates over 35, and in three Raipur (24·64), Bhandara (21·35) and Chanda (20·69), they were under 25 per 1000. In five districts the rates were higher than the quinquennial means, but in only two, Bhandara and Chanda, did the number of deaths exceed the number of births. The average birth-rate in the towns, 29·21, was slightly in excess of the average in rural areas, 28·80. The percentage of male to female births throughout the province was 105·94, ranging in the districts from 113·41 in Burhanpur, to 101·94 in Damoh.

The number of deaths registered was 227,853, and the death-rate was 23·46, as compared with 57·82 in 1900, and the quinquennial average of 45·56 excluding zamindaris, computed on the larger population of the 1891 census. In only eight of the twenty districts were the rates over 25 per 1,000, the highest being 29·44 in Jubbulpore, 29·34 in Wardha and 29·11 in Burhanpur; while in four districts rates below 20 per 1,000 were recorded—Bilaspur 19·85, Murwara 19·81, Seoni 19·33 and Mandla 18·77. The urban death-rate was 28·49 against 23·02 in rural areas, the excess being due to smallpox, bowel complaints and diseases registered under the heading "all other causes." Among the towns, Burhanpur (37·04) Arvi (35·78) in the Wardha district, and Sehora (35·39), in Jubbulpore, had the highest death-rates, and low rates were registered in Pauni (16·66), Saugor Cantonment (16·30), Garhakota (15·16) and Bilaspur (14·05).

Hindus, who constitute the vast majority of the population, died at the rate of 20·67 per 1,000, Muhammadans at the rate of 26·66 and "Other Classes" at the 40·12.

The death-rate was 2·35 in January, and fell fairly steadily to a minimum of 1·45 in July, a gradual rise in August and September was followed by a sudden rise to the maximum of the year, 2·50, in October, followed by rates of 2·39 in November and 2·47 in December.

The death-rate among male infants was 246·41 for every 1,000 born, and among females 224·63. In every age-period the male death-rate was higher than the female, the average being 25·21 among males and 21·77 among females.

Berar.—The number of births recorded in Berar in 1901 was only 83,762, and the birth-rate was 30·8 per 1,000, as compared with 31·3 in the previous year, and a quinquennial mean of 38·2, calculated upon the *higher* census population of 1891. The falling-off in the number of births, as compared with the numbers recorded in recent years, which is attributable to the famine and few marriages in 1901, is common to all the districts; the highest rates being 34·3 in Wun and the lowest 28·9 in Ellichpur. The percentage of male to female births in the province generally was 104·6, ranging from 107 in Ellichpur to 101·6 in Basim.

But the year was a very healthy one, and the total number of deaths registered was only 75,080, equal to a death-rate of 27·6 per 1,000, which is almost exactly a third of the rate in 1900, and nearly 21 per 1,000 less than the five years' mean. In the districts, the rates varied between 30·2 in Akola and 25·2 in Wun. In the towns the variation was greater, between 38·3 in Anjangaon and 18·3 in Ellichpur, the average being 29·6 against 27·2 in rural circles.

The vast majority of the population are Hindus, and among them the death-rate was 27·7, followed by 27·4 among the small population of Christians. Muhammadans died at the rate of 25·6, and "Other Classes" at the rate of 29·3.

The monthly death-rate, which was 2·7 per 1,000 in January, fell steadily with the exception of a slight rise in April, to a minimum of 1·3 in June, after which the rise was fairly rapid to a maximum of 3·4 in October, followed by a gradual fall to 2·8 in December.

The death-rate of male infants was 205·30, and of females 187·92, per 1,000 born, respectively, while boys and girls over one and under five years of age died at the rates of

68·0 and 61·4 per 1,000 living. At the age-periods between 10 and 40 years of age, the female death-rates were the higher, the average for males at all ages being 27·9 and for females 27·4 per 1,000.

Madras.—The total number of births recorded in Madras was 935,749 or 113,450 fewer than in 1900, the deficiency being attributed by the Sanitary Commissioner of the Presidency to the depressing influence upon fecundity of the high prices of food grains in 1900. The birth-rate was 25·1 per 1,000, considerably less than the birth-rate of the preceding year, and less than the five years' average calculated upon the same population. The highest birth-rate was 37·1, registered in the urban district of Madras, and this was followed by rates of 31·8 and 30·5 in Tinnevelly and Tanjore, respectively. In Ganjam (20·5), North Arcot (19·1) and Madura (16·1) the lowest rates were recorded. The average urban birth-rate was 30·7 per 1,000 as compared with 24·6 in the rural circles. The percentage of male to female births averaged 104·2, and ranged from 108·1 in Ganjam, where registration is very defective, and 106·2 in Godavari and North Arcot, to 99·8 in Nellore, a district in which the population is nearly a million and a half, and where the percentage in 1900 was 102·2.

The recorded deaths in 1901 numbered 796,140, or about 25,000 more than in the preceding year, and the death-rate was 21·3 per 1,000. The variation in the districts was extreme, from 55·5 in Madras, where the highest rates under the headings fevers, dysentery and diarrhœa and 'other causes' were registered, to 10·9 in Madura. In Chingleput (30·1), South Canara (26·0) and Tanjore (24·7) the rates were comparatively high, and in Ganjam (14·8) and Vizagapatam (14·6) they were very low. Plague occurred in fifteen of the twenty-two districts, but the death-rates recorded as due to it were low, except in the cases of Bellary (1·1) and Salem (·7). The urban death-rate was 32·7 or 12·3 per 1,000 in excess of the rural rate. The town of Vaniyambadi in the Salem district suffered very severely from both plague (64·1) and cholera (27·7), the total death-rate being 141·3, including 14·6 per 1,000 registered under 'other causes.' In Bellary the death-rate was 48·1 per 1,000, including 12·1 from plague and 26·6 from 'other causes.'

The death-rate among Christians was 17·0, among Hindus 21·6 and among Muhammadans 22·5. The death-rate among 'Other Classes' was reported to be 4·4 per 1,000 and furnishes an example of defective registration; in Ganjam the population of 'Other Classes' is 277,377 and the number of deaths reported among them was 53; in Cuddapah the 'Other Classes' total 353 and the deaths recorded 124.

The monthly death-rates were lowest in March, April and May, highest in October, November and December.

The death-rates among infants were 174·54 and 159·39 per 1,000 males and females born, respectively. At all age-periods except 15–20, the male death-rates were the higher, the averages being 22·2 for males and 20·5 for females.

Coorg.—The number of births in the small province of Coorg was 3,401, as compared with 4,542 in 1900, and the average birth-rate, which ranged in the districts from 28·34 in Padinalknad Taluk to 14·50 in Kiggatnad Taluk, was 18·83. The rates are said to be necessarily low owing to the large number of temporary immigrants included in the census population. The percentage of male to female births was 98·31, varying between 103·80 in Yedenalknad Taluk and 92·18 in Padinalknad Taluk.

The number of deaths recorded was 6,590, and the death-rate was 36,49 varying from 43·89 per 1,000 in Padinalknad Taluk and 29·35 in Kiggatnad. The death-rate in the towns was 53·18, ranging from 83·82 in Verajendrapet, where dysentery and diarrhœa caused a death-rate of 20·79, to 23·13 in the village of Fraserpet. The greatest mortality occurred in June, May and July, and the least in October and November. Muhammadans died at the rate of 39·62 per 1,000 and Hindus at the rate of 36·08. The death-rates among male and female infants were, respectively, 287·07 and 283·38 per 1,000 born. At all age-periods, except 15–20 and 30–40, the male death-rates were the higher, the averages being 36·80 among males and 36·09 among females.

Bombay.—The depressing effect of conditions of famine on fecundity is strikingly shown in the Bombay registration returns of 1901. The number of births recorded was only 465,647, a smaller number than any registered since 1882, and no less than 177,067 fewer than the mean number recorded in the ten years ending with 1900. The birth-rate was 25·19 per 1,000. In seventeen of the twenty-five districts the birth-rates were lower than the death-rates, the excess of the latter over the former reaching the excessive

proportions of 60·30 per 1,000 in the city of Bombay, and 48·56 per 1,000 in Belgaum The highest district birth-rates are 33·43 in Khandesh, 32·41 in Broach and 31·89 in Ahmednagar. In ten districts the birth-rate was below 25 per 1,000, the lowest being 17·48 in Bombay, 15·06 in Hyderabad and 8·36 in Thar and Parkar, in which district it is stated that the extraordinarily low rate was due to the exodus of the people on account of the scarcity. The urban birth-rate, 22·72, was lower than the rural rate by 2·85, the deficiency being in part due to families leaving the towns on account of plague, and in part to the greater deficiency of registration in the towns. The effect of famine on the birth-rate, which began to show itself in April 1900, reached its climax in March 1901, when only 24,840 births were registered, after which the numbers gradually rose to the maximum of 54,554 in October; and in December the number of births recorded was rather higher than the average number recorded in that month.

Compared with the appalling mortality of 1900, when the recorded deaths numbered 1,318,783, the total of 1901 looks small, but the number of deaths recorded, 686,134, is greater than the number recorded in any other year. The death-rate of the Presidency was 37·12, varying in the districts from 77·78 in the city of Bombay, to 13·21 in Upper Sind Frontier. The rates were over 50 per 1,000 in four districts besides the city of Bombay, namely, Belgaum, 71·91, Dharwar, 71·26, Ahmedabad, 52·68 and Broach, 50·38. In Bombay, Belgaum and Dharwar the excessive rates resulted from plague, but in Broach the death-rate, including only 6·50 per 1,000 ascribed to plague, was due to high-rates under 'fevers' and 'other causes'; while in Ahmedabad it was due to the excessive rate of 43·69 under 'fevers.' Low rates were recorded in Ratnagiri (21·10) and in all the Sind districts, except Karachi. The death-rates in the towns averaged 57·85 against 34·01 in the rural areas. The plague death-rate in the towns was 15·15 against 5·7 in the districts; the fever rates in town and country were 14·46 and 16·0; the dysentery and diarrhœa rates, 4·35 and 3·09, and the 'all other causes' rates 22·33 and 7·83. Plague deaths occurred in thirty-six of the sixty-three towns, the death-rates from this cause being in many instances enormous, *e.g.*, in Dharwar the plague death-rate was 58·67 and the total death-rate 105·58, in Hubli, also in the Dharwar district, the plague death-rate was 51·12 and the total death-rate 83·99, in Gadag-Bettigeri the plague death-rate was 47·96 and the total death-rate 75·33 per 1,000. In the small town of Gogha, in the Ahmedabad district, the death-rate was 177·37 per 1,000, including 27·72 from plague, and 103·38 ascribed to fevers.

Parsis died at the rate of 27·14 per 1,000, Muhammadans at the rate of 28·10 and Hindus at the rate of 39·69.

The greatest mortality occurred in the months of December, November and October, and the least in May, June and July.

The registered mortality among male infants was 198·13, and among female infants 189·28 per 1,000 recorded births, respectively. In the age-periods, 5–10 and 15–20, the female death-rates were the higher, the average death-rates of the sexes being 37·52 among males and 36·70 among females.

Burma.—The number of births registered in Lower Burma was 177,865, or 6,682 more than in 1900, and the birth-rate was 32·07. The rates in the districts varied greatly, from 40·68 per 1,000 in Henzada, 38·72 in Tharrawaddy, and 37·80 in Sandoway, to 27·83 in Akyab, 25·94 in Thaton, and 25·33 in Toungoo. The lowest rate recorded was 12·70 in the urban district of Rangoon, where the proportion of males to females is as 2·3 to 1, and registration is apparently very defective. In the towns generally, birth registration is more defective than in the country, rates varying between 61·73 and 44·91 in the little towns of Zigon and Kawkareik, and 18·61 in Akyab; where females constitute less than a fourth of the population. The average urban birth-rate was 24·19 against 33·14 in the rural circles. The average percentage of male to female birth was 107, ranging from 112 in Pegu and Mergui to 104 each in Prome, Henzada and Thayetmyo.

There were 120,565 deaths registered, as compared with 122,714 in the preceding year, yielding a death-rate of 21·74 per 1,000. The urban district of Rangoon, from which the lowest birth-rate was returned, furnished the highest death-rate, 33·17 per 1,000, being followed at a distance by Hanthawaddy (25·25), Henzada (24·45) and Mergui (24·22). The lowest death-rates were recorded in Toungoo (15·77), Tavoy (16·64) and Thaton (17·02). While the average recorded urban birth-rate was much lower than the rural rate, the average death-rate was higher in the towns (29·99) than in the country (20·62). The variation in the town death-rates, though considerable, was not excessive, the highest being 38·42 in Pegu, and the lowest 16·52 in Sandoway.

In each of the last six months of the year the number of recorded deaths was greater than in any of the first six months; the lowest death-rates being recorded in March, May and April, and the highest in August, July and December.

The death-rates among infants were 206·59 and 168·61 per 1,000 born respectively. In every age-period the male death-rate was the higher, the averages being 23·06 for males and 20·24 for females.

Christians, of whom the total number was 133,540, are shewn to have died at the rate of only 11·97 per 1,000, but this is manifestly wrong, for among 27,330 Christians in Toungoo district, only 50 deaths were reported. Buddhists and "Others" died at nearly the same rates, 22·13 and 22·36, respectively, but the death-rate of Hindus was 25·59 against only 16·26 among Muhammadans. The principal reason for this difference appears to be the fact that the majority of the Muhammadans are resident in the district of Akyab, where registration is very bad; and it is probable that mortality among Hindu immigrants is unduly high.

In Upper Burma births and deaths were registered in thirteen towns, and deaths were recorded in certain rural tracts also. The average birth-rate in the thirteen towns was 37·66 per 1,000, and the average death-rate 33·27; the birth-rates varying between 47·38 in Pakokku, and 23·36 in Minbu; and the death-rates between 35·80 in Mandalay, and 16·31 in Pagan. The Provincial Sanitary Commissioner is satisfied with the progress of registration in all the towns except Minbu; but, while the numbers returned may be not far short of the truth, greater accuracy in details might be expected; for instance, although the average percentage of male to female births in the thirteen towns was 105, the percentages ranged from 145 in Minbu, to 90 in Myingyan and Salin.

Ajmer-Merwara.—The average number of births recorded during a year in Ajmer-Merwara in the quinquennium ending with 1900 was 15,431; in 1900 the number registered was 7,958, and in 1901 the number has fallen to 7,679, equal to a birth-rate of 16·10 per 1,000. The percentage of male to female births recorded was 119·15, as compared with 123·79 in 1900. The number of deaths registered in 1901 was 15,798 against 65,067 in the preceding year, and the death-rate 33·13 per 1,000 as compared with 119·97 in 1900. The urban death-rate was 39·06, as compared with 30·91 in the country. Hindus and Muhammadans died at the rates of 35·42 and 31·56 respectively. Male infants died at the rate of 236·9 per 1,000, registered births and female infants at the rate of 254·6. Between the ages of 10 and 40 females died at a greater rate than males, the averages for the sexes being 33·15 for males and 33·10 females.

History of the Chief Diseases.

Cholera.

Just as in the case of enteric fever, one of the chief difficulties with regard to suspected water examined, is the rarity (not so great as in the case of enteric fever) of finding the true microbe and the frequency of finding microbes like it. There is the same kind of doubt as to how far these cholera-like microbes may be dangerous, and whether they may not be a stage of existence of the true comma. Heim has called attention to the value of a blood decoction as an addition to his original enrichment process for the detection of the cholera microbe in water. The statements of Firth that in India he found the danger signal of cholera in water to be the presence of a large number of fluorescent vibrios, and that previously healthy waters in which these vibrios suddenly appeared were certain to cause an epidemic of cholera in a few weeks, require confirmation. It has been pointed out in Egypt from actual experience that specimens of stools, &c., which in the fresh state readily yield the vibrio, may after the time spent on a twenty-four hours' journey to a laboratory give but a negative result. The use of potassium permanganate for the disinfection of wells has, as usual, been frequently resorted to during the year; but though opinion on the whole is favourable, there is no proof of its efficacy; and it may be mentioned that recent experiments tend to throw discredit on present chemical means of water purification. The importance of flies in the spread of the disease, symbiosis as a

factor in cholera causation, and the fresh vigour which cholera is supposed to have acquired about the year 1817, are all old points which have lately been brought up again, L. Rogers has extolled the leucocyte count as a simple and rapidly applied guide in diagnosis and prognosis.

Deaths from Cholera in the different Provinces in India from 1877 *to* 1901.

§ Including 30 deaths in Cantonments.
‖ Excluding Zamindaries.
¶ In selected towns only.

Cholera in India.—The cholera mortality of India in 1901 was reduced from that of 1900 by over 67 per cent., and was less than in four of the six years preceding, of which 1900 had the highest ratio, and 1898 and 1899 the lowest. There was a decrease in every month of the year, except January; but the diminution was greatest in March-August. Every province had a lower ratio, except Madras and Coorg, the difference being greatest in the Central provinces and Berar. The three highest ratios were, in order, those of Bengal, Assam, and the United Provinces. No province was quite free. Further details are given in the paragraphs below.

Burma.—In Lower Burma during the ten years, 1892–1901, the highest registered death-rate from cholera was 1·89 per 1,000 in 1897 and the lowest 0·53 in 1893, the ratio of 1901 being 0·64. The districts which suffered most in 1901 were Prome, Thongwa, Myaungmya, and Amherst; and urban mortality was highest in Kyaiklat, Danubyu, Yandoon, and Pegu. Two districts and sixteen towns returned no deaths. The fact that the fatality comes to 98 per cent. of cases indicates that non-fatal cases were not often reported. In the selected towns of Upper Burma only one death was recorded.

Assam.—The mortality from cholera in Assam was less than half the average for the last fifteen years; and the actual number of deaths was lower than in any year of the preceding nineteen. I wish, says the Sanitary Commissioner, I could think that this favourable result was due to improved sanitation and efforts made by the people to cleanse their surroundings, but I cannot. There was a succession of small epidemics in the Cachar and Kamrup districts. In the Lakhimpur district more than half the deaths

occurred in tea-gardens, and there was also a smart outbreak, causing 182 deaths, in the railway camp at Tipling Ghat. The Nowgong district, which had been severely visited in 1900, registered but few deaths in 1901. The highest district ratios were those of Kamrup, Cachar, and Lakhimpur ; and the highest town ratios those of Silchar, Dhubri, and Karimganj. For tea-gardens the ratio of mortality was 2·17 per 1,000. The number of tea-garden cooly immigrants fell off considerably, but the proportion of deaths occurring amongst them while in transit from Goalundo to the port nearest to the place of their employment also diminished ; and the Sanitary Commissioner ascribes this to greater precautions taken on the steamers and to greater care exercised not to ship infected coolies. This may be so, but rates as low have occurred before.

Bengal.—Only six times in the twenty-four years preceding is the number of deaths from cholera in Bengal seen to be less than in 1901, though the 1900 mortality had been the highest on record. Nevertheless, the disease visited every district except Ranchi in 1901, attacked 18,806 villages, and assumed an epidemic form in 43 areas. The highest district ratios were those of Puri, Cuttack, and Balasore all in the Orissa Division ; and the highest town ratios those of Maheshpur, Ghatal, and Revelganj. Excepting in Puri, Balasore, Midnapur, Chittagong, and Hazaribagh, the district mortality was everywhere lessened, and only ten districts had a death-rate of over 2 per 1,000. In the absence of fuller explanation, the remarks of the Sanitary Commissioner on the connexion between deficient rainfall and cholera are somewhat obscure. The medical officer of Puri traces the outbreak in epidemic form to the contamination of the drinking water at Balunga *mela* held in Pipli circle ; and the medical officer of Balasore to importation by pilgrims *en route* to and from the Jagannath festivals at Puri ; but in neither case are materials offered for the formation of a critical opinion on these statements. The disease prevailed throughout the year in Orissa, was never prevalent in Chota Nagpur, and in Bengal proper was somewhat severe in January-May and in December. "Good results" were reported from twelve districts from the disinfection of wells with potassium permanganate. In the Mazaffarpur district applications were actually made for a supply of the disinfectant, but in some other districts its use was strongly objected to. The subject of inoculation will be mentioned below. Among the European seamen of the port of Calcutta there were 5 deaths from cholera, and 63 in the native floating population.

United Provinces.—The number of deaths from cholera in the United Provinces, though much lower than in 1900, was otherwise higher than in any year since 1896 ; and the ratio was higher than that of the lustrum. The mortality reached its maximum in October. The highest district mortalities were those of Hardoi, Rai Bareli, and Lucknow, all in the Lucknow Division ; and the highest town mortalities those of Sahatwar, Bilgram, and Barhaj. The districts of Almora and Hamirpur were free, and the number of deaths in Dehra Dun was only five. Details are not given of the reported efficiency of potassium permanganate for the disinfection of wells ; but the benefit in times of cholera is mentioned of the appointment of a couple of Brahmans or Khsattriyas to draw water for all from an uninfected or disinfected well.

Punjab.—In only five years, of which two were 1894 and 1898, in the twenty-four years preceding were there fewer deaths from cholera in the Punjab. The ratio also was only one thirty-second of the quinquennial mean. The mortality in the preceding year had been heavy. The districts of Umballa and Karnal and the towns of Jagadhri and Sujanpur had the highest mortality ratios. Only 35 towns or villages in 32,834 registered deaths, and the maximum number was 36 in Jagadhri in the Umballa district. The first three cases there were among persons who had returned from Hurdwar, where cholera was reported to be prevalent. Though the disease did not assume a severe epidemic form, it was present in the town for about two months.

North-West Frontier Province.—In the North-West Frontier Province also cholera was much diminished, the ratio being 80 per cent. below that of the lustrum. The districts of Kohat and Bannu were free throughout the year. Most of the cases occurred in the Peshawar district, and chiefly in Tangi village, the first of the 62 cases in Tangi being that of a man who had come from the Swat village where cholera was prevailing. A few cases also appeared in neighbouring villages. The first of Peshawar city's 24 cases was derived from Tangi ; and it is stated that after ninety-one wells had been treated with potassium permanganate the disease stopped.

Bombay Presidency.—In the Bombay Presidency the cholera mortality ratio was about 74 per cent. below the mean of the previous five years, and about 92 per cent. less than in 1900. Sind was entirely free, and Gujarat nearly so. In January cholera was continuing in five districts from the previous year, the epidemic reached its maximum in April, and in July a further extension of the disease took place. The affected area included 916 villages out of 25,846, and the mean percentage of deaths to attacks was 60·16. Much the highest district mortality ratio was that of Dharwar, and the three next highest were all from the same Registration District. The highest town ratios were those of Kaladgi, Ranebennur, and Gokak, all in those districts. The Deputy Sanitary Commissioner of the Registration District says that the wide diffusion of the disease in the preceding year made it impossible to ascertain the origin of the first cases of 1901, that the disease has been endemic for the last ten years, and that, as usual, it was propagated by human intercourse from village to village amid grossly insanitary conditions.

Berar.—Only in two years of the preceding twenty-four, 1880 and 1898, had there been fewer cholera deaths than in 1901. The ratio was 99·9 per cent. below that of the preceding year, and also much below the quinquennial mean. In the district of Akola there were 43 cases with 16 deaths. The outbreaks in the villages of Rail and Dhad were attributed to contaminated water, while that at Dongergaon originated at a feast held by Dheds, thirteen being attacked and two dying. Potassium permanganate was employed to disinfect all wells and polluted sources.

Central Provinces.—A reduction of 99·8 per cent. took place in the cholera mortality of the Central Provinces, and only once in the preceding twenty-four years had the number of deaths been less. The ratio of 1901 was also over 99 per cent. less than the lustral mean. The districts of Narsinghpur and Nimar and the town of Khapa had the highest mortalities. The outbreak at Narsinghpur was ascribed to the arrival of pilgrims from Mathura, where cholera was prevalent. The origin of the first outbreak at Nimar could not be traced; but in the second the disease was imported by a wedding party from an infected village in Indore. The first case in Raipur was a woman returning home from a pilgrimage. Sporadic cases occurred in Nagpur and Chanda.

Madras Presidency.—An increase of a little over 18 per cent. took place in the mortality of the Madras Presidency as compared with that of the previous year, and a slight increase as compared with the quinquennial mean. The number of deaths had been higher only in three of the preceding twenty-four years. The highest district ratios were in Salem, Anantapur, Cuddapah, and North Arcot; and the highest town ratios in Vaniyambadi, Arcot, Ramnad, Calicut, Ambur, and Nandyal. The Sanitary Commissioner points out that the towns which chiefly suffered in mufassal areas, have water supplies open to fæca pollution, and that in Madras town the inhabitants are allowed to supplement the public water-supply by the use of innumerable wells sunk in a foul subsoil and open to pollution. He also complains that local authorities are not yet alive to the necessity of taking action before the cholera is actually upon them, and that they are prone to allow economy to interfere with efficiency.

Coorg.—There had been no cholera in Coorg for two years when it broke out again in 1901, causing 58 deaths. The first outbreak occurred towards the end of April in the Mercara taluk, the disease being imported by a Mappilla coming from South Canara. A second slight outbreak occurred in November, the disease making its first appearance in villages on the South Canara border. In other cases also the infection was traceable directly or indirectly to South Canara.

Cholera inoculation.—At Purulia during the year 3,335 inoculations were performed among the cooly emigrants proceeding to the tea gardens of Assam, 58 among those proceeding to Trinidad, and 60 among the population of a Manbhum village during an outbreak. Out of 275 uninoculated coolies on board the steamers plying between Goalundo and Dibrugarh in February and March, 8·36 per cent. got cholera, ten of the cases ending fatally; while out of 414 inoculated coolies only 1·2 per cent. contracted the disease, and none died of it. If inoculations were performed elsewhere, the fact is not mentioned.

Small-pox.

The mortality ratio of India from small-pox was the same as in 1900, and somewhat below the quinquennial ratio. All the months of the year, except the first three and August, showed a greater number of deaths. The total number of deaths in the preceding year (excluding Mysore and Upper Burma) had been 84,780, and in the year before that 49,113. There was very little small-pox in the towns of Upper Burma. The increase in Assam was chiefly due to several outbreaks in the Sylhet district; and the medical officer reported that most, if not all, of these followed the visits of inoculators, and that the people objected to be vaccinated with bovine lymph. The provincial Sanitary Commissioner supports him in calling for a more extended application of the Act against inoculation. Not for at least 25 years had there been so high a mortality from small-pox in Bengal as in 1901, and it was higher in every district except eight. Inoculation, says the civil surgeon of Cuttack, in which the disease seems to be increasing in virulence, is carried on throughout the district, and thus the disease is spread: when the outbreak of smallpox is mild in character, children are wilfully exposed to the disease; and when these return to their own villages an outbreak results, which is not confined to those thus exposed, but spreads among the unprotected with disastrous results. In the port of Calcutta there were three deaths among European seamen and three in the native floating population. In the United Provinces and Oudh, on the other hand, the rate was the lowest on record, and no district or town had a high rate. Nearly two-fifths of the deaths from smallpox in the Punjab were reported from the districts of Montgomery and Jhang; while the Kangra district, said to be the best vaccinated in the province, had, as usual, a low mortality. Some of the municipal towns suffered very severely, and the Sanitary Commissioner complains that the municipal committees do not take enough interest in vaccination. The civil surgeon of Bannu in the North-West Frontier Province brought to the notice of the authorities that the large number of cases in the district was due to inoculation freely carried on by Pathan inoculators, and steps were taken to put a stop to the dangerous practice. Though the death-rate in the Bombay Presidency was not high, Kanara and Ahmedabad were the only collectorates free from the disease. At the outward and inward inspections 30, and on board vessels lying in the harbour or docks of Bombay city 4, cases of smallpox were detected. The death-rate in Berar was low. The disease was more prevalent in all the districts of the Central Provinces except Betul and Chanda. The epidemic was a continuation of the previous year's outbreak, and began to wane in June, but waxed again in October-December. The Madras Sanitary Commissioner considers that the high mortality in the town of Cochin was due to the fact that it adjoins an area under independent native administration. In Coorg the death-rate from smallpox was high.

Statement showing the deaths from Small-pox registered in the different Provinces by Months during the year 1901.

Plague.

For India as a whole there was a great increase in plague mortality, an increase of over 67 per cent. It will be seen in the table on page 102 that the principal provinces of India, with their native states, shared in the increase. On the other hand Assam, the North-West Frontier Province, Baluchistan, Ajmer-Merwara, Central India, Berar, and Coorg returned no deaths, though the two last had each a fatal "suspicious case." The plague of the Central Provinces and Burma was entirely imported.

A few fragmentary notes will now be given on various points regarding plague, before the mortality for the disease in each province is considered.

Difficulty of Diagnosis. Rats and other Animal—The chief points mentioned by Power as having been brought out by Low in his study of Plague reports from all parts of the world, are the comparative slowness with which plague becomes acclimatized to new conditions; the difficulty of diagnosing the first occurring cases of plague, owing to its mimicry, as it were, of indigenous maladies; and the apparently varying relation of rats to the spread of the disease. The following words of his might have been written from a study of the Indian reports: "The records to which Dr. Low has had access, though they go to confirm belief that as regards plague man and rat are reciprocally infective, fail completely in affording sufficient data for determining the degree to which man is in danger through the rat. So far as plague ashore is concerned, it would appear that in particular localities man and the rat suffered from plague coincidently, that in other localities man suffered before the rat, and that in others again the rat suffered antecedently to man. Further, it would appear that when in a particular district the one (man or the rat) has suffered plague antecedently to the other, the interval between invasion of the first and of the second species has been often a long one, extending sometimes over weeks and months. Finally it would appear that plague may prevail largely among men without rats becoming conspicuously affected; and conversely that the disease may cause large mortality among rats of a locality while neglecting to attack its human inhabitants. As regards plague on shipboard very similar facts were forthcoming. The disease does not, under conditions of sea transit, appear to be at all readily conveyed from the rat to man or from man to the rat. On the one hand ships plague invaded for several weeks in the persons of crew or passengers have come into port with the rats on board them seemingly altogether exempt from disease; and on the other hand, ships infected with plague-smitten rats have, after voyages of considerable duration, arrived at their destinations wholly free from plague as regards crew and passengers." That rats play a part in the spread of the disease is considered by Kolle and Martini as the most important lesson of the present outbreak in the world. The rat and not man, says Davies, is the primary sufferer from plague, and it is by the rat, and perhaps by the rat alone, that plague is spread; human plague is preceded by the epizootic, and the real danger to importing countries lies with plague rats, not with plague-stricken men; the infected rat is mainly distributed through the world by ships; local diffusion is but little due to contact with plague-stricken persons, and the only prophylactic of much value is the destruction of rats and their nests, burrows and habitual haunts; the recrudescence of plague in a city means that the disease is probably present as an epizootic, and that its further spread is independent either of the sanitary condition of the locality where the sporadic human cases have happened to occur, or of the incubation period of plague in the human subject; "contacts" now mean not those who have been exposed to human plague but those who may become exposed to rat infection. So, according to Kolle and Martini, rats are to plague what water is to cholera, plague is as much (if not more) a rat disease as a human pest, and plague is a disease of rats which only occasionally attacks man. Maxwell in Changpoo estimated that men were attacked about a week after the rats. In Manilla about 1·7 per cent. of the rats captured were found infected with plague. But in Glasgow, though rats were plentiful, they seem to have escaped, and nearly 300 of them were examined for the plague bacillus in vain. Again, Edington and also Schilling have described epidemics among rats not due to the real plague bacillus; Klein has demonstrated in the bodies of dead rats taken from a ship arriving at Bristol a microbe like the plague bacillus but with cultural characters between those of *B. coli* and those of *Bact. lactis aerogenes*; Tartakovsky has pointed out that the common pseudotuberculosis bacillus of rodents is very like the plague bacillus; and Galli-Valerio urges that confusion in the diagnosis of plague by the inoculation of guinea-pigs might arise from the fact that the *B. pseudo-tuberculosis rodentium* might be present in the guinea-pigs, the two bacilli exhibiting many points in common. An important case was reported in which a ship

sailing from a port not at that time known to be infected had at the end of 29 days of the voyage a minority of her rats affected; and two men ultimately fell ill. Another ship left an infected port and was disinfected, but plague appeared in 27 days from the time of leaving the infected port, and infected rats were found on board. From January to March of one year at Marseilles the rats of 7 out of 44 ships were found infected. Kossel and Nocht, on the other hand, found dead plague rats on board a steamer in which no human plague cases had occurred. Other animals which for the first time have been found to be infected are bats, wallabies, and kangaroos, and in all the infection was supposed to have been conveyed by fleas.

Fleas.—When hungry fleas, says Zirolia, are allowed to suck, they void blood in streams two or three times, to make room for filling themselves again and again, and thus sow the bacillus over the skin; also the bacilli remain alive and virulent in the fleas for about a week, and during this time may be found in their excrement. Laveran and Mesnil have shown that the flea seems to take a part in the transmission of trypanosoma from rat to rat. The life cycle of the flea, according to Howard, is complete in 17 days. In Egypt, Kolle personally experienced the possibility of taking away fleas on his clothes from plague dwellings without being any the worse, and he and Martini think the importance of insects in the spread of plague has been over-estimated by Simond and Ashburton Thompson; their own experiments with animals were negative; fleas containing plague bacilli went over to sound animals without infecting them; they agree with Nuttall and Galli-Valerio: the flea question appears to them rather academical, as there are so many ways in which infection might pass from rat to man; the fact of the transference of infection from rat to man is more important than the question as o how it is transferred. In the words of another, that the parasites of the plague-infected rat, although charged with plague bacilli, do actually cause plague in man has not been proved, but is the only link in the cycle of evidence actually wanting. Goodall remarks that the parasites of the mammalia are rarely interchangeable. In former reports it has been shown how Galli-Valerio failed to make rat fleas bite him. He has lately published an account of what has been done on the subject, and concludes that so far from its being possible to assert as an established fact that plague is transmitted to man by the bites of the fleas of rats and mice, and that this is the most frequent and important means of infection, it requires to be demonstrated not only that the fleas pass from rats and mice to men but that they pass from rat to rat. In these views Galli-Valerio has, of course, the support of Nuttall.

Measures against rats and insects.—The chief advance in the method of securing the destruction of rats and insects appears to be the Clayton process, which could be used on land as well as on shipboard, and the most recent experimental evidence in its favour is that of Calmette and Hautefeuille, who used a ship in their tests. The Clayton gas is a mixture of the sulphurous and sulphuric anhydrides. Haldane also reports favourable results from carbonic oxide, and others have found carbonic anhydride of use. But these methods require to be perfected, in view of certain difficulties which are met with in practice. For rooms Fulton and Stokes recommend hydrocyanic acid gas. The method of Danysz continues to meet with faint praise, though Wiener, like Bronstein, states that its virulence can be raised by the use of alkalinized medium. The same procedure can be used for Issatschenko's and Grimm's bacilli, which are considered to be identical.

The bacillus. Hardiness, viability, or survival.—Caldas holds that the plague bacillus is but a rat colon bacillus of high virulence. Klein has shown that the bacillus of Danysz and that of Gärtner are indistinguishable except by habitat, both belonging to the colon group; and in the discussion on his paper Foulerton and MacFadyean were quite prepared to consider them identical. Again, Voges states that in the dead bodies of rats there is some difficulty in distinguishing the bacillus of Danysz from the plague bacillus. In the same way, Tartakovsky and also Galli-Valerio have pointed out that the *B. pseudo-tuberculosis rodentium* is very like the plague bacillus morphologically and culturally; and the former found that it forms stalactites indistinguishable from those of the plague bacillus. Another caution as to bacillary diagnosis is given by Rosenfeld, who finds that other bacilli give involution forms on salt agar, though a careful and experienced observer can distinguish those of plague from the others. Galli-Valerio, however, points out that the involution forms of the glanders bacillus are very like those of the plague bacillus, and suspects that in both cases the so-called involution forms are really normal developmental forms. Sata found that up to the fourth day after death t

bacilli could be isolated from bodies by cultivation, but that animals could still be infected for about 16 days; and the experience of Kolle and Martini was that they perished in 10–14 days. Old cultures that had been preserved for from twenty months to four years were discovered by Schultz to be still virulent.

Experiments on animals. Mode of entrance. Mode of spread.—The delicacy of the skin-rubbing method (referred to in former reports) for the detection of the plague bacillus suspected to be present in any medium has been extolled by Kolle and Martini, Dürck, and Fritsche. The first-named found it demonstrate the presence of that bacillus when cultivation and ordinary inoculation had failed. Fritsche states that it is the only one of hæmorrhagic septicæmic group which kills when so inoculated, and that it enters by the lymphatics, while anthrax enters by the hair follicles, and the pneumococcus by the capillaries. Kolle and Martini's experiments showed that passage through the rat, mouse, or guinea-pig, especially if the infection had been effected by inhalation, enhanced the virulence of the plague bacillus, but not passage through the rabbit. As Kolle and Martini say, while plague patients do not directly infect, except in the pneumonic form, they are nevertheless dangerous. Speaking of his experience in South Africa and India, Blackmore asserts that in no case was their direct evidence of conveyance from man to man, but that rats and fleas, and sometimes soil, were necessary intermediaries. Voges, like others quoted in former reports, found the bacillus in the sputum in certain cases, even after convalescence had been established, and even when there was no pneumonia discovered the bacillus in the mouth and pharynx. The danger of this to men and rats is obvious. Schottelius also states that the bacillus may be found in the sputum and bronchial secretion of the majority of plague cases, at least when they have become septicæmic before death. The view that man derives the disease from the soil—the order of infection being rat, soil, man—is strongly urged by Farrar.

Mahamari.—Whether it be the case or not, as quoted by Sticker, that the homes of the original conveyers of plague are discovered in the colonies of the Asiatic marmot; the observations of Chayton White have made it almost sure that *mahamari* is plague. In studying an outbreak in Garhwal, he was able to show with an approach to certainty that the disease had not been imported from the plains; and he succeeded in obtaining from patients smears and cultures in which the plague bacillus was identified by Hankin, Haffkine, and himself. Specimens were sent to Europe for further examination.

Bengal.—There was increased prevalence of plague throughout Bengal, severest in Calcutta, in all the districts of the Patna Division except Chumparan, in Monghyr of the Bhagalpur Division, and in Hazaribagh of the Chota Nagpur Division. As in the previous year, the Patna Division, and especially the district of Patna, suffered more than any other, and it also suffered more than in 1900. The disease was first imported into a village near Barh in September, 1899, and gradually spread, chiefly in the most densely populated areas. The epidemics in the Saran, Gaya, and Monghyr districts were continued from 1900. The districts of Shahabad, Muzaffarpur, Darbhanga, Sonthal Parganas, Hazaribagh, Palamau, and Manbhum were infected during the year from the districts of Patna, Gaya, and Saran. The direction in which plague spread, says the Sanitary Commissioner, is very characteristic; it generally followed rapidly along trade routes and main routes, and very slowly indeed in purely agricultural parts. Seasonally the epidemic followed the same course as in the preceding year; it was comparatively quiescent during the hot weather and rains. With regard to the district of Saran, however, it is noted that while the towns attacked remained almost free in the second half of the year, in the rural areas the disease continued throughout the year. The people readily resorted to evacuation, but were against disinfection. Inoculations were performed in the Saran, Monghyr, Gaya, and Patna districts; but only in Gaya district was the number very large, some of the educated natives in Gaya town being themselves inoculated and promoting the measure. The Sanitary Commissioner asserts that not infrequently houses shortly after disinfection have been reinfected by persons or rats. He is of opinion that man is the chief agent in the spread of the disease, and that inoculation is a more useful measure than disinfection.

City and port of Calcutta.—There was the usual exacerbation in the beginning of the year, attaining its height in the week ending 23rd March. It began earlier than in 1900, reached its maximum earlier, and subsided more rapidly. As before, Ward V. was the first to show the recrudescence. The epidemic was, if anything, less severe; and the apparent increase is attributed to greater success in finding cases. There was a special tendency among Mussulmans to conceal cases, especially female cases The facts

were believed to indicate that the infection is one of locality, though the cases do not always occur in the same houses in successive outbreaks. One of the most striking features of the epidemic was the marked intensity of the outbreaks in dal and grain godowns. Though the Special Health Officer himself does not believe in the agency of rats, his assistants are strongly impressed with the importance of the part they play. The Special Health Officer believes that the disease is but slightly contagious, and that both rooms and men are probably infected through the medium of airborne dust; that dark haunts of the disease which cannot be disinfected should be destroyed; that otherwise disinfection is the best measure against plague, because it renders the house at once habitable, and reinfection is rare, at least in the same epidemic or within six months. One hundred and eight vessels arriving from plague-infected ports were boarded, but no cases of plague were found, though four of the vessels were "suspected ships," and were quarantined until they had been disinfected. No "infected ships" arrived in port, and no cases were detected among the crew or passengers of outward-bound vessels, though some of the rejected persons may have afterwards developed the disease.

* Late North-Western Provinces and Oudh.

(*a*) Patiala only.

(*b*) This table has been submitted by the Chief Plague Medical Officer, Punjab, and differs from that shown in the Sanitary Report for 1901.

United Provinces.—Plague was prevalent in the districts of Benares, Ballia, Allahabad, and Jaunpur; small outbreaks occurred in Agra, Mirzapur and Azamgarh; and scattered cases were reported from Partabgarh, Ghazipur, Sitapur, and Gorakhpur. In the middle of January the disease broke out almost simultaneously in the Benares and Ballia districts. The first outbreak in Benares prevailed chiefly in the city and in a village in its vicinity and lasted to May, while the second began in October and subsided in December. In the city the classes trading in food-stuffs were particularly affected. Inoculation was purely voluntary, and the number inoculated up to August was only 1,172. The second outbreak was confined to the city, and is believed to have proceeded from foci established during the first. The first case in Ballia is understood to have occurred at Raniganj, a large market town having trading relations with the infected Saran district, and by the end of the year the disease had appeared in 66 villages. In the Allahabad district the source of the infection was not traced, but the first cases appeared in March in a village near Mau Aima, and Mau Aima had suffered from plague in the preceding year. The disease had fairly established itself in Allahabad city in September. At the end of the year plague was still gaining ground in the district. To Jaunpur the pest spread in the month of March. The Agra cases were, with one exception, confined to the city and its suburbs, and the disease was successfully stamped out. Mirzapur was infected by refugees from Benares. In four villages of the district of Garhwal 23 fatal cases of *mahamari* were observed.

Punjab and Kashmir.—The enormous increase of mortality from plague in the Punjab is ascribed by the Sanitary Commissioner to the relaxation of all compulsory measures; and the disproportionate mortality among females to the fact of their being more in the infected houses than the men. But the monthly progress of the disease was not unlike that recorded in other provinces. The great majority of the deaths were reported in the districts of Jullundur, Hoshiarpur, Gurdaspur, and Sialkot. In the Jullundur district a great extension of the disease occurred in March, and though the number of cases diminished in the hot weather, there was not the usual complete cessation. The Hoshiarpur district remained free till March, when it was reinfected from the Jullundur district, and after that the disease did not entirely disappear. The plague of the Gurdaspur and Sialkot districts was continued from the preceding year, and increased greatly in the earlier months of 1901. In all these districts the second extensive rise began in September. The vast majority of the cases were of the bubonic type, though some were pneumonic or septicæmic. A mild and less fatal form is said to have prevailed in two tahsils where inoculation had been largely performed. As far as the Chief Plague Medical Officer could obtain information, infection of villages seemed in nearly all cases to be due to human intercourse, directly or by means of clothes, &c., and in no instance could proof be got of the introduction of the infection by rats, though in many villages large numbers of dead rats were seen before the disease had spread.

Plague in the Jammu province of Kashmir was imported from the adjacent British districts of Gurdaspur and Sialkot. It began in February in the village of Rara, and up to the 7th July fifteen more, including the town of Samba, had become infected. On the 21st August the disease, which had died down, reappeared in the village of Chhanni, and afterwards in other villages; and towards the end of December it reached the city of Jammu. The epidemic was at its worst in the months of November and December. It is stated that infection was generally observed to pass readily from patients to their attendants or even visitors, so long as the former remained in their dark and ill-ventilated houses; but that after their removal into tents or chhappars in the open, the number of attendants who took the disease from their sick charges was strikingly insignificant. About twice as many women were affected as men, which was ascribed principally to their being more in the house than men. The Kashmir plague authorities believe "dessication" to be superior in efficacy to chemical disinfection.

Madras Presidency, Madras city, and Mysore.—In the Madras Presidency, the towns of Vaniyambadi, Bellary, and Ambur suffered most. Bellary was infected by cases imported from the Bombay Presidency and concealed by householders. Elsewhere the infection was derived directly or indirectly from Mysore territory, no less than 120 cases having been removed from trains at the Jalarpet inspection station alone. In connection with certain investigations of one of the civil surgeons, the Sanitary Commissioner suggests that the possibility of primary infection of the intestine through water may perhaps require investigation. The question has also been raised in Madras whether under special circumstances certain kinds of snakes may not be susceptible to plague.

There was no epidemic in the city of Madras. No information is available as to the progress and features of the plague in Mysore, but plenty of correspondence as to the measures which were or ought to have been taken there.

Bombay Presidency.—In the Bombay Presidency the number of towns and villages affected was 1,582 against 587 in the previous year ; and the mortality was the highest recorded since the first appearance of the disease in 1896. All the collectorates in the presidency were affected except Thar and Parkar, Larkhana, and Upper Sind Frontier, those suffering most being Belgam, Dharwar, Satara, and the city of Bombay, with death-rates between 34 and 19. Then came Karachi, Broach, Surat, Poona, and Thana, with rates between 7 and 4 per 1,000. In the collectorate of Khandesh the number of deaths rose from 8 to 2,676, and in that of Kolaba from 140 to 1,116.

City and port of Bombay.—In the city of Bombay plague was present throughout the year, the maximum being in March, with a secondary maximum in September. During the month of January there was a rapid increase in the epidemic pervading every district. The people had grown so accustomed to the plague that there was absolutely no panic of any kind ; the plague staff met with no opposition ; and in many cases the people showed that they appreciated disinfection and evacuation. With equanimity and resignation they bore the epidemic, which from the 26th February to the 19th March exceeded in virulence all previous epidemics. Points brought out in the report of the Municipal Commissioner are that those actually engaged in combating the plague were impressed by the part played by rats ; that disinfected houses were frequently reinfected, sometimes, at least, by rats ; and that houses which had cases in 1900 were apt to have them again in 1901. On more than one occasion dead rats sent to the Plague Research Laboratory were found to contain plague bacilli. It was noticed that vagrants were not so frequently attacked as formerly.

At the outward and inward inspections and on board vessels lying in the harbour and docks, 73 cases of plague were detected ; 51 at outward inspections, 3 at inward inspections, and 19 in harbour. Among the passengers and crew sent to the Port Observation Camp, 51 developed plague ; but in consequence of the rigour of the examination and disinfection, few persons actually suffering from fully-developed plague symptoms attempt to leave Bombay by sea. Three cases occurred on outward vessels. The question of the method of clearing ships of rats was under consideration.

Rajputana.—The village of Bali in the Marwar State contains a large number of banias who carry on business with Bombay, and there is constant intercourse between the two places. On the 25th of January a bania arrived from Bombay, and walked about the village during the day, but was found dead next morning. In February plague broke out, and lasted till the 15th April. In March the disease appeared in Sewarhi, about eight miles from Bali, and did not stop till the 15th May. In the two villages 6,820 inoculations were performed. Sixteen of the inoculated persons were subsequently attacked, and eight died.

Hyderabad State.—There was less plague in His Highness the Nizam's dominions than in any year since 1897, and during half the year they were free from it. One of the cases in February and the cases in September and October were imported. The districts of Aurangabad and Kopbal recorded 145 out of the 149 deaths. The plague of Aurangabad lasted from January to March, declining from January, and broke out again in December. That of Kopbal did not appear till near the end of the year.

Fevers.

The fever mortality of India (calculated on the census population of 1901) was 18·1 per cent. lower than that of the previous year (calculated on the census population of 1891), and 10·5 per cent. below the quinquennial ratio ; the number of deaths falling from 4,860,790 to 4,174,919. The decrease affected all the months of the year, except February, August, and December, and was greatest in October. If the mortality of each of the two years had been calculated on the census population of 1901, the decrease would not have been quite so great. Than Lower Burma only Madras had a smaller death-rate, and the ratio was less than usual. A pamphlet was issued to local authorities and medical subordinates on the etiology, prevention, and treatment of malaria. The sale of quinine from post offices and by private vendors and vaccinators

was somewhat less than in the previous year. Urban fever mortality in Upper Burma was greatest in October, November, and December. In Assam fevers were more prevalent than in 1900, and this is believed to be the reason why the sales of quinine increased. The total given for fevers includes 5,856 deaths from kala azar, of which 4,792 occurred in the district of Darrang and Nowgong. The disease has almost disappeared from the Goalpara district, and is much lessened in Kamrup. Sibsagar and the North Lakhimpur sub-division have escaped. In Darrang a few fresh villages have become affected; but in Nowgong only chronic cases come for treatment, and some parts of the district are reported free. The extent of the disease in the Sylhet district was not discovered until a thorough inspection had been made by a hospital assistant specially deputed for the purpose. Hislop has reported the finding of cases of Malta fever among natives in Assam; while Bentley, from a study of cases of *kala azar*, has come to the conclusion that *kala azar* is Malta fever. But this conclusion has been assailed by L. Rogers and by Dodds Price, both adversely criticising the clinical and therapeutic evidence offered, and the former specially condemning the serum testing

procedure and results.* The Sanitary Commissioner of Bengal believes that the "fever" mortality of the province was unduly raised by the inclusion of plague deaths; that the fevers prevailing throughout Bengal are chiefly malarial in nature; and that the comparative immunity of urban areas is due to better water-supply arrangements and greater facilities for medical aid. There was a falling off in the number of packets of quinine sold; but the largest sales were effected in the months of usually greatest fever prevalence. In the native floating population of the port of Calcutta 33 deaths took place from fever, and 2 from enteric fever among the European seamen. In the United Provinces the mortality, a great deal of which was really due to malaria, but some to plague, &c., was somewhat reduced. The Sanitary Commissioner is inclined to think that money will be better spent in improving surface drainage and filling in tanks and depressions than in organizing so-called mosquito-brigades. Nearly five times as many packets of quinine were sold as in the previous year, the most successful agency being the post office; and the price was reduced towards the end of the year. In most districts of the Punjab there was a decrease of death from fever, especially considerable in those districts which had suffered most severely in 1900. The people of the five districts where mortality was highest had suffered from a severe famine, immediately followed by a destructive epidemic of malarial fever; so that in their weakened state of health they were unable to resist the

* See also Bassett-Smith in J. T. M. of 2nd February, 1903, page 37.

attack of a mild epidemic in 1901. The attention of civil surgeons and district officers was called to the necessity of draining or filling up all small pools of water in the vicinity of towns and villages, and of encouraging the use of quinine. Arrangements for the free distribution or sale of quinine in the Punjab do not seem to be very far advanced. Besides the jail and regimental cases, it is probable that unrecognized cases of cerebrospinal fever may have been occurring in the civil population. The fever mortality in the Bombay Presidency was low; and the high ratios of Ahmedabad and other four collectorates were considered to be, to a great extent, due to famine causes. Four cases of enteric fever and 227 of other infectious fevers were detected by the Bombay Port Health Officer. The fever mortality in Berar was much reduced. In the Central Provinces too the mortality fell greatly. Practical measures are contemplated for the prevention of malaria. Meantime the sale of quinine has been increased; schoolmasters, stamp vendors, and patwaries have been added to the list of agents; and the price has been reduced. The fevers which caused death in the Madras Presidency are considered to be chiefly malarial; and every effort, though apparently not often with much success, was made to induce local bodies to act upon present knowledge as to the part played by the mosquito. The Sanitary Commissioner offers evidence of the occurrence of enteric fever even among pure natives, and of water-pollution sufficient to account for it. According to him, statistics in the Madras Presidency show that the more perfectly water-supply has been extended to a town, the less is the fever rate, notwithstanding that, in the absence of drainage systems, it is exceedingly likely that anopheles pools have been much increased. Coorg registered an increase of fever mortality; and the greater prevalence of fever, as well as the reduction in the price of the drug, may have been a causative factor in the marked increase in the sale of quinine.

Dysentery and Diarrhœa.—The mortality ratio for bowel complaints for India was less than half that of the preceding year, and the number of deaths fell from 523,292 to 247,054. The ratio was also about 26 per cent. below the quinquennial mean. The decrease ran through all the months of the year, but was most marked in July-September. The towns returning the highest mortalities in Lower Burma are said to be those which

generally head the list, and in which, in addition to overcrowding and its attendant evils, there exist permanent sanitary defects in connection with conservancy, drainage, and water-supply. As in former years, the rates for the Darrang, Sibsagar, and Lakhimpur districts are much heavier than those for Goalpara and Kamrup; and investigation has not yet succeeded in suggesting a satisfactory explanation. The highest mortalities of Bengal were those of the same sixteen districts as in the preceding year, though with

changes in order. Bowel-complaints generally prevail among the scantily clad people in the cold weather, probably as a sequel to malarial fever. One death occurred among the European seamen, and five in the native floating population of the port of Calcutta. It is usual for Garhwal to have the highest mortality among the districts of the United Provinces. The Sanitary Commissioner of the Punjab connects the decrease of dysentery and diarrhœa with the diminution of malarial fever ; and the highest mortalities of 1901 were lower than those of the same districts in 1900. In the Bombay Presidency the decrease was considerable, was shared in by all the months of the year, and was probably connected with the diminished area of famine. In Bera the decrease was great. All the districts of the Central Provinces, except four, had lower death-rates. The higher ratio in municipal towns than in rural areas is explained by the Sanitary Commissioner of Madras as illustrating the effect of the aggregation of human beings upon filthy and sewage sodden soil, with contaminated water-supply. The increase in Coorg may have been due to the concurrence of cholera. Nearly half the total occurred in May, June, and July.

Vaccination.

Vaccination in India.—During the year under review the conditions which affected the work of the Vaccination Department so adversely in 1900–01 had for the most part passed away. Scarcity, however, still lingered in Bombay ; and except in the Central Provinces there was a great extension of plague in the affected provinces, particularly in Bombay and the Punjab. In Bombay it was considered prudent not to push vaccine operations in the plague-affected areas ; but in the Punjab, in view of the repeated recrudescence of the disease, it was resolved not to suffer the infected districts to remain unprotected from small-pox any longer, so in future years, it may be hoped, that vaccination will again progress.

The aggregate number of operations performed in 1901–02 was 8,036,414, which is 162,052 more than in the preceding year, but 88,893 less than in 1899-1900. Six provinces divide the increase, but in unequal shares. Work progressed most in Bengal and Madras ; and in the United Provinces, Assam and Berar the increase as compared with the preceding year was satisfactory ; but in Ajmer-Merwara the increase was inconsiderable. Five provinces show a further falling off. Chief among them is Bombay where the decrease is nearly 140,000 ; then comes Burma with a decrease of nearly 60,000 ; and then the Punjab (with which for purposes of comparison with last year the figures relating to the new North-West Frontier Province are here included) with a decrease of more than 40,000 ; then the Central Provinces with 30,000 ; and, lastly, Coorg where the decrease was upwards of 2,000. The presence of plague and the effect of famine caused the decline in Bombay and the Punjab, and the effects of famine affected work in the Central Provinces. No reasons are given for the falling off in Coorg, nor is the serious decline in the work in Burma fully explained. It may, however, be inferred from the Burma report that the decrease in the reported number of operations performed is mainly due to the prevention of falsification of their returns by the vaccinators.

The number of primary operations performed during the year was 7,358,744, or 123,724 more than in 1900–01, and the number of re-vaccinations was 677,700, or 38,328 more than in the previous year. There was a great falling off in the number of re-vaccinations in Assam, from 20,247 in 1900–01 to 9,412 in 1901–02.

The average degree of success obtained in the country generally was somewhat higher in both primary operations and re-vaccinations than in the preceding year, the percentages being 94·97 and 65·5 in 1901–02, against 94·5 and 64·4 in 1900–01. The highest percentages of success in primary cases were claimed in Ajmer-Merwara, 99·21, and Bengal, 98·01 ; and the lowest in Burma, 90·11, and Madras, 89·41. The percentages of success in re-vaccination ranged from 83·93 in the Central Provinces, 81·55 in the United Provinces, and 81·09 in Assam, to 51·0 in Burma, and 18·3 in Berar.

Included in the foregoing figures are the 210,277 operations performed at dispensaries. That total is 4,927 in excess of that of 1900–01, and in most provinces, except notably Coorg and Burma, there was a small increase. The vast majority of the operations, 145,661, were performed in Bengal, and except in Assam, the Central Provinces, Madras, and Burma, dispensary vaccination is either non-existent (Berar and Ajmer) or trifling in amount.

The proportion of the population protected during the year varied between 49·15 and 44·46 per 1,000 in Coorg and Assam, respectively, and 21·49 per 1,000 in Bombay, the average proportion being 31·3, as compared with 31·8 in 1901; the apparent falling off being due to the computation of the ratio for 1901–02 on the higher population figure of the 1901 census.

* For the calendar year 1901. † For Lower Burma only.

If we suppose that 40 children were born for every 1,000 of the population, 33·41 per cent. of them were protected by vaccination during the year, against 33·9 per cent. in 1900-01, the percentages varying between 53·88 in Berar, and 19·19 and 12·53 in Burma and Coorg, respectively.

The average number of operations performed by a vaccinator in the year ranged from 2,867 in Berar, to 950 in Bengal and 723 in Ajmer-Merwara.

The average small-pox mortality was ·40 per 1,000 against ·41 in the preceding year. The death-rates ranged in the provinces from 2·48 per 1,000 in Coorg, where there were 449 deaths, and ·63 in the Central Provinces, where there were 6,081, to 02 in the United Provinces, where the deaths numbered 981, and ·01 in Ajmer-Merwara, where they numbered only 4.

The aggregate cost of the department was £75,484 or about £1,400 less than in the preceding year; and the cost of each successful case varied between 9 annas and 4 pies in Bombay, and 1 anna and 2 pies in Bengal, the average being 2½ annas, or 1 pie less than in 1900-01.

Nature of the vaccine used.—The methods of carrying on vaccination in the different provinces are not uniform. In Madras, Assam, Berar and Burma calf lymph is used, generally mixed with either lanoline or glycerine. In Bengal fresh and lanolinated calf lymph is used, but the majority of operations are performed with human lymph taken directly from the arm. In the Punjab buffalo calf lymph made into a paste with sterilized vaseline is the vaccine in use. In Bombay and the United Provinces glycerinated calf lymph is used to a limited extent, but the vast majority of the operations are done with human lymph taken directly from the arm in Bombay, and preserved on ivory points in the United Provinces. In the Central Provinces human lymph, fresh calf lymph, calf lymph mixed with glycerine and calf lymph mixed with lanoline are all in use.

The length of time that preserved calf lymph will retain its efficiency, and whether lanoline or glycerine is the best preservative are questions regarding which diversity of opinion still exists. So far as the somewhat unsatisfactory data at hand enable one to form an opinion, lanolinated lymph will keep better than glycerinated lymph, but probably much depends upon the lymph used and the conditions of manufacture, while when different lymphs come to be tested the effect of the varying skill of vaccinators must not be left out of account.

Both glycerinated and lanolinated lymph will, however, keep sufficiently long in any season of the year to admit of distribution in any province from a central depôt situated in the province. In more than one of the provincial reports there are complaints regarding the quality of the lymph-supply. This should not be. The encouragement of vaccination creates an obligation to provide vaccine, the use of which not only affords protection against small-pox, but is free from danger and inconvenience.

Bengal.—The total number of operations recorded in Bengal was 2,662,826, against 2,346,311 in the previous year, and 2,252,521 in 1899–1900. Primary cases numbered 2,529,778 and re-vaccinations 133,048, the corresponding figures in the previous year being 2,227,942 and 118,369. It is satisfactory to note that while a larger number of operations were performed, the standard of success rose from 97·8 to 98·0 per cent. in primary work, and from 59·2 to 67·07 per cent. in re-vaccinations.

Striking increases occurred in some districts, notably in Mymensingh which shows a rise of 43,215 cases; in two other districts the work increased by over 30,000 operations each. Four districts only show a fall, Dacca being the chief of these, where the decline was by 11,934 cases; this is, however, due to a sub-division of the district having been transferred to Faridpur.

It is computed that 32·06 per cent. of the infants available were protected in the province as a whole, while in the towns more than double, or 70 per cent., were successfully vaccinated, compared with 60 per cent. during the previous year. The ratio returned for towns is, however, in the present condition of registration, considered to be of doubtful value.

The results to the credit of the department during the year 1901–02 are satisfactory, especially as the superior staff, owing to other demands, was unable to extend the requisite amount of supervision to the work of vaccinators, who being mainly recruited from an ignorant class exercise but little influence with the people. The system under which licensed vaccinators do much of the work in Bengal has, it is said, rendered the department unpopular, while it is difficult for the vaccinators to recover their fees. The working of

the department is, however, being examined, and the question whether it would not be well to replace the existing licensed vaccinators by a paid agency is engaging special attention. The introduction of well considered measures of reform will no doubt effect improvement in the work done, and the opening of a training school for vaccinators at Cuttack, which has already passed out some trained vaccinators, will help to provide efficient men.

Small-pox prevailed in epidemic form during 1901, the ratio of deaths having been ·50 per 1,000 of population against ·29 per 1,000 in 1900. To this cause is in some measure due the increased amount of work recorded during the year under report.

The following table shows the results obtained with (1) human lymph and calf lymph, (2) free from admixture and (3) mixed with lanoline.

	Primary Vaccination.		Re-Vaccination.	
	No. of cases.	Percentage of success.	No. of cases.	Percentage of success.
Arm to arm	1,961,650	98·16	63,893	68·83
Calf lymph without admixture	323,884	98·56	35,134	75·74
Lanoline lymph	244,244	96·07	34,021	54·79

These results are an improvement on those recorded in the preceding year.

The inadequacy of the lymph supply, which is reported to be impeding work in many parts of the province, has been again mentioned by the Sanitary Commissioner who urges the establishment at an early date of the Animal Vaccine Depôt at *Pusa*, and this has been approved by Government. The establishment of another such depôt in Orissa is also recommended.

The Calcutta and Darjeeling Depôts continue to be worked satisfactorily, the lymph supplied from the former having been reported to be of very good quality.

The Nepal Darbar and the Sikkim State received, respectively, 675 and 560 grains of lymph during the year, but no detailed results were reported. For vaccination in Bhutan 50 grains of lanoline paste were supplied.

Inoculation is said to be very prevalent in Orissa and the punishment meted out to offenders being inadequate, it has so far not proved deterrent.

Assam.—The total number of operations in the province was 280,827, as compared with 271,466 in 1900–01, and 272,265 in 1899–1900. Primary cases numbered 271,415 against 251,219 in 1900–01 and re-vaccinations 9,412 against 20,247. While, therefore, primary work increased, re-vaccination declined, but the recorded percentages of success rose in both classes of work, from 96·0 and 80·0 per cent., respectively, to 97·48 and 81·09 per cent. The effect of local measures satisfactorily augmented the outturn of work done at dispensaries, and the steady increase in the number of primary operations performed by the tea garden agency was maintained.

In the province the protection afforded to infants is represented by 32·6 per cent. of the births recorded during 1901, compared with 25·4 per cent. protected during the preceding year; while in 11 towns, where the compulsory Vaccination Act continues in force, 80 per cent. of the available number of infants were successfully vaccinated, against 70 per cent. during the previous year. At Nowgong, one of the eleven towns, no less than 94 per cent. of the available children were protected, a result due to Captain McNaught's personal efforts.

The amount and quality of work done at the Animal Vaccine Depôt at Shillong during the year under report was the largest and most satisfactory on record. The total number of tubes loaded with vaccine was 395,317, as compared with 387,557 in the previous year. The quality of the lymph was generally excellent, although it is to be noted that the first supply in the Darrang District proved to be of inferior quality, probably due to the heat of the weather at the time it arrived in the district.

Inoculation is unfortunately still carried on, although it appears to be widely practised in only the Surma Valley Districts. Several outbreaks of small-pox in the Cachar and Sylhet Districts were distinctly traceable to inoculation. It is significant of the attitude

of the people that in one sub-division the inhabitants petitioned the Chief Commissioner to stop vaccination and authorise inoculation. In the opinion of the local Administration the province is not yet ready for the suppression of inoculation by law, and other than coercive measures must be depended upon to secure a discontinuance of the evil practice in Assam.

United Provinces of Agra and Oudh.—The steady progress which has attended vaccination in the United Provinces during the past five years was maintained, with the result that a total of 1,579,795 operations were performed by the special staff during the year, against 1,549,233 in 1900–01, and 1,511,436 in 1899–1900. Including 400 operations at dispensaries against 176 last year, the total for the province was 1,580,195. Of this number, 1,490,996 were primary cases and 89,199 re-vaccinations, the ratios of success being 96·02 and 81·55 respectively, as compared with 95·2 and 82·5 in the preceding year. It is satisfactory to note that both the quantity and quality of the work shows an improvement. The hill districts are specially well vaccinated, the people being anxious to be vaccinated and re-vaccinated three or four times.

The number of successful primary vaccinations in municipalities fell from 113,275 in 1900–01 to 110,455 in 1901-02, the decline being attributed to a smaller number of births during the latter year. Of 88,366 children under one year computed to be available in the towns, 85,640 were successfully vaccinated.

Bovine lymph depôts were, as usual, maintained at Lucknow, Bahraich and Allahabad. The outturn of work has not been stated, but the quality of the lymph was apparently good. Pure calf lymph and lanolinated calf lymph were both used, but not to any large extent.

Orders have been issued for the construction of the new bovine lymph depôt at Patwa Dangar (six miles from Naini Tal), which when in working order may be expected to provide a good lymph supply for the entire province.

Punjab.—Excepting the year 1899-1900, the decline in the number of operations in the Punjab has continued year by year since 1896-97. During 1901-02, the primary operations numbered 511,121, and re-vaccinations 157,023. These figures exclude those relating to the districts transferred to the North-West Frontier Province since November 1901, and are therefore not comparable with the figures relating to the Punjab published in previous reports. The percentages of success were 93·92 in primary vaccinations, and 58·47 in re-vaccinations, both lower rates than were recorded in the previous year.

The causes of the continued decrease in the amount of work done were practically the same as in the year 1900-01—a low birth-rate and sickness consequent on scarcity, which also affected the supply of buffalo-calves ; the continuance and spread of plague in the province necessitated the total suspension of vaccination in certain badly affected tracts, while the employment of the Deputy Sanitary Commissioner and vaccinators on plague duty interfered with the conduct of vaccination work.

The local government has decided that the existence of plague ought not to lead to the infected areas being left unprotected against small-pox, and efforts are to be made to carry on vaccination in those areas irrespective of the presence of plague.

The improvement of the prospects of the subordinate staff of the department by the introduction of a reorganization scheme which took effect from the 1st September, 1901, should result in better work and the recruitment of a better class of men in future.

No addition was made to the list of towns in which the Compulsory Vaccination Act is in force, and the administration of the law in many of them leaves room for criticism. But the improvement of vaccination in towns is engaging attention, and efforts are being made to persuade municipal committees to introduce the Act, and also to encourage the vaccination of children where the Act is not applied.

No details of work in the Native States of the province have been furnished, but it is stated that in Patiala and Kapurthala a decrease has occurred in consequence of the prevalence of plague.

Particulars are wanting with respect to the work of the provincial lymph depôt. Vaccination with vaseline lymph proved less successful than with fresh animal lymph, but this is attributed to the fact that the former was used in the warmer months when results are always poorer.

Circumstances compelled the postponement of trials with glycerine lymph, and also the conduct of experiments as to the protective power of vaseline vaccine paste. The re-appointment of a whole-time Deputy Sanitary Commissioner, and the provision of the necessary apparatus, will now admit of definite action being taken to carry out experiments.

North-West Frontier Province.—This province appears in this report for the first time, the figures for the districts which constitute it having hitherto been included in the returns for the Punjab. As in the Punjab, there has been a decline in the work of the Vaccination Department, the total operations being 70,993, as compared with 78,479 in 1900–01 and 81,583 in 1899–1900. The decline has occurred in the primary work only, re-vaccinations having increased during 1901–02 to nearly double the number performed in either of the two previous years. The details of the work done during 1901–02 show 63,321 primary cases and 7,672 re-vaccinations, against 73,614 and 4,865 respectively in 1900–01 : the percentages of success being 91·03 and 75·18 in 1901–02 and 92·75 and 66·87 in 1900–01.

It is stated that 2,174 vaccinations were performed in the Sherrani country, but whether these are excluded from the total returned for the province is not apparent.

It is of interest to note that the practice of vaccination is beginning to be appreciated by the tribesmen across the border, and the Bonerwals bring their children into British territory to be vaccinated.

Central Provinces.—The total number of operations performed by all agencies during the year 1901–02 amounted to 425,392, a decrease of 30,005 on the total recorded during the preceding year. Of the total, 350,484 were primary cases and 74,908 re-vaccinations, while in the year 1900–01 the corresponding figures were 385,493 and 69,904 respectively.

The foregoing figures include the work of the Feudatory State Vaccination Establishment and all the dispensary operations in the province. Excluding the latter, there were 269,270 primary operations in British districts and 68,738 in the Feudatory States during 1901–02, the corresponding figures for 1900–01 having been 303,559 and 67,004 respectively. The percentage of success declined in British districts from 97·13 to 95·87, and in the States from 96·23 to 95·93.

The re-vaccination work, however, exhibited an improvement, the number of cases in British territory rising from 52,054 to 53,409, but the percentage of success declined slightly from 84·94 to 83·56. In the States re-vaccinations increased from 14,979 to 18,818, and the ratio of success from 84·02 to 86·34 per cent.

The cause of the decrease in primary work in the British districts is attributed to a low birth-rate, the poor health of the people, and the closure of famine camps. In the States the increased outturn of work was due to the extension of vaccination to certain villages of the Patna State, where it had never before been attempted, and also to the prevalence of small-pox in parts of the Kalahandi State.

In dispensaries in British territory the number of primary vaccinations fell from 12,985 to 10,665 and re-vaccinations from 2,479 to 2,322. The percentage of success in the former, however, rose in the year under report from 92·34 to 94·62, and in the latter from 60·31 to 74·29. The causes of the reduced outturn of work are the same as noted above for the province. Owing to the absence of returns of dispensary vaccination from no less than seven Feudatory States' institutions no valid comparison of the work of the year 1901–02 with that of 1900-01 is possible.

The Vaccination Act continued in force in 35 out of a total of 45 municipalities, and in those 73·40 per cent. of the available children under one year of age were successfully vaccinated. The ratios vary considerably in the several towns.

As in 1900–01 nearly two-thirds of the operations were performed with animal lymph, and the percentage of success, 95·63, was identical with that returned the previous year. With glycerinated lymph the steady improvement noted last year was maintained, the percentage of success being 90·96 against 86·97 in 1900–01 ; while with lanolinated lymph the percentage of success declined from 99·51 to 88·81. The ratios of success obtained by the use of human (arm-to-arm) lymph were practically the same in both years, 95·11 and 94·66 in 1900–01 and 1901–02 respectively.

Berar.—Some of the ground lost owing to famine conditions during 1900–01 was regained during the year 1901–02, when a total of 120,418 operations were performed, or an increase of 12,630 over the total of the preceding year. There was improvement in both primary vaccination and re-vaccination, the numbers having risen from 74,707 and 33,081 in 1900–01 to 82,296 and 38,122 respectively in 1901–02. The percentage of success in primary operations was 96·6, which is the same as the ratio returned last year, and in re-vaccinations 18·3, against 20·9.

In the province 92·8 per cent. of the available infants were vaccinated ; and in 10 municipal towns 4,620 out of 4,922 infants were successfully operated upon.

Lanolinated lymph, manufactured at Amraoti, was used exclusively, and, while quite as efficacious as the pure calf lymph used in the previous year, was more economical.

Madras.—The total number of operations performed in the Presidency during 1901–02 inclusive of that at dispensaries, was 1,325,106 against 1,257,883 during 1900–01 ; the department thus maintaining the increase recorded last year. There was an increase in both primary operations and re-vaccinations, due partly to the extension of vaccination in local fund areas, and partly to the recovery from the falling-off brought about by the plague scare. Still, in nine districts there was a decrease, in explanation of which incompleteness of staff is urged as the main reason, while insufficiency or inertness of lymph is also advanced in some cases. The remedy for the former lies with local boards, while as to the latter the establishment of the new vaccine depôt which is being built ought to remove all cause of complaint.

The ratio of success in the total work is practically identical with that of the previous year, viz., 89·4 and 69·0 per cent. during 1901–02 and 89·2 and 69·7 during 1900–01 in primary vaccination and re-vaccination respectively.

Notwithstanding the comparatively satisfactory state of affairs which these figures exhibit, it has been shown that the increased work of recent years has not kept pace with the growth in the population, particularly in respect of the infant population. In municipalities an average of 66 per cent. of the available children were afforded protection, although in 47 towns, against 42 last year, the ratio was 75 per cent. But the number of children said to be available in towns is believed to be much fewer than was actually the case, and the effort made to secure better registration and more work on the part of vaccinators will, it is to be hoped, tend to improvement.

Coorg.—Notwithstanding the prevalence of small-pox in 1901–02, the number of operations declined from 12,049 in 1900–01 to 9,772, of which 8,416 were primary cases. The cause of the decrease has not been stated. In the dispensaries 320 persons were vaccinated against 669 in 1900–01. The percentages of success attained in 1900–01, 93·2 and 74·7 in primary operations and re-vaccinations respectively, were practically maintained in 1901–02, when the percentages were 93·5 and 74·2.

The vaccination of children above six months of age is compulsory in five municipal areas in Coorg, and from the results returned it is considered that the provisions of the law were adequately enforced.

Bombay.—The total number of operations in the Presidency was 521,706, and the decrease as compared with the returns of the preceding year amounted to 139,333 cases. The decline occurred in both primary operations and re-vaccinations, and is stated to be mainly due to a low birth rate consequent on the incidence of both famine and plague. The quality of the work done, however, shows an improvement, as the percentage of success in primary cases was 91·9 against 90·8 in 1900–01, and in re-vaccinations 59·9 against 56·9. The percentage of cases in which the results were unknown fell to 6·71 per cent. compared with 8·12 per cent. in the previous year.

The work in native states fell off considerably, from 133,720 primary cases in 1900–01 to 51,356 in 1900–01, and from 9,756 re-vaccinations to 8,404. The success in the former was 95·2 per cent. as compared with 92·6 in 1900–01, but in re-vaccinations it was slightly less—69 5 against 70·0.

That more work was done in the dispensaries in 1901–02 than in the preceding year was chiefly due to an increase at Bushire.

The quality of the lymph supply is reported to have been good—human and bovine lymph were both used. The ratios of success attending the use of former ranged in the several registration districts from 93·37 to 86·8 per cent. With the latter the ratios ranged from 89·8 to 70·88 per cent.

Glycerinated lymph was used in the Presidency circle only, with a success of 73·4 per cent., and lanoline paste in the southern registration districts only, the rate of success being 79·4 per cent.

Burma.—The number of operations performed in the province was 360,224, which represents a decrease of 59,687 cases as compared with the preceding year. Of this total, 333,657 were primary cases and 26,567 re-vaccinations, as compared with 392,305 and 27,606 respectively during 1900–01. The percentage of successful primary operations was very slightly lower, viz., 90·1 against 91·2 in 1900–01, but the success in re-vaccination was greater, 51·0 as compared with 49·9. No reasons for the reduced

outturn of work have been advanced, but it may be gathered that more effective supervision of the operators and closer examination of the returns have prevented falsification of the latter, which even now the Local Government declares to be unworthy of trust.

Inoculation is said to be freely carried on throughout the province, but the best way to induce the Burman to accept vaccination is to make it effective. The unfortunate occurrence of a conviction by a township officer of an inoculator being thrown out on appeal to the chief court has had an undeniably hampering effect on the department. The average small-pox mortality in Burma during the quinquennial period ending 1900 was 7·74 per 1,000 of the population, as against 4·02 in the quinquennium ending with 1895, so that the need of fostering the work of vaccination is abundantly evident.

There were 20,347 children available for vaccination in towns ; of these 17,757 were successfully vaccinated—probably a marked improvement on the real results of the previous year.

Calf lymph is used generally throughout Burma, resort being made to arm-to-arm vaccination when the supply of animal vaccine fails. Of the three lymph depôts, that at Taunggyi was closed in June, 1901, owing to a failure in the supply of calves, and the establishment transferred to Rangoon. In Rangoon, also, the supply of calves failed owing to the prevalence of cattle disease, and a new depôt was opened at Meiktila in February, 1902. Work is being carried on there in a hired house, but the construction of a suitable building will soon be begun.

Besides the locally made vaccine, supplies of vaccine were obtained from Bangalore, which generally proved more active than that manufactured locally.

Ajmer-Merwara.—There has been little improvement in this small British tract in Rajputana in the vaccination work recorded during 1901–02 as compared with the year 1900–01, when there was a great falling away from the results of the previous year. The number of operations performed during the year under report was 10,841, of which 10,831 were primary operations and only 10 re-vaccinations, the corresponding figures during the preceding year being 10,660 and 21 respectively. The success in primary operations was the same in both years, viz., 99·2 per cent. ; in re-vaccinations it rose from 61·9 to 80·0 per cent.

Civil Sanitary Works.

Bengal.—Excluding Calcutta, there were 155 municipalities in Bengal, an increase of two, namely, Budge Budge and Panihati, as compared with the preceding year.

The total income of the municipalities during the financial year ending on the 31st March, 1901, including an opening balance of £40,100, was £332,000, or £19,500 more than in the previous year, the increase being due to larger receipts from loans, grants from provincial and local funds, and contributions from private individuals.

The total municipal expenditure on sanitary purposes was 44·48 per cent. of the income, or £147,000, including £16,400 on water-supply, £13,400 on drainage, and £77,520 on conservancy ; the expenditure under the last two headings showing increases, as compared with the previous year, of sums of £4,684 and £5,468 respectively. On original sanitary works, as opposed to maintenance, the total sum spent was £28,040, only 13 municipalities devoting over 10 per cent. of their incomes to this purpose, while a large number spent less than 1 per cent.

Among the more important works completed or in progress were the following :— The Manicktolla municipality caused pipes to be laid from the Calcutta main at Sealdah, along the Beliaghatta road, for the extension of the filtered water-supply. The Krishnagar municipality caused the silted up Anjona channel to be re-excavated and bridged, at a cost of £988, to secure the efficient drainage of the town. At Darjeeling the fencing in of the water-supply catchment area at Senchal was completed. The Patna municipality carried out the scheme for flushing drains in the Pirbahar Mohulla at a cost of £2,800. At Gaya a tramway line, for the removal of filth, was constructed and maintained by the municipality at a cost of £839.

In rural areas the total cost of sanitary works completed or in progress was £40,346, against £33,100 in the preceding year.

Only one meeting of the Sanitary Board was held during the year, but the usual consultative work was carried on by the circulation of files among the members.

The principal subject of discussion at the meeting was the septic tank system of sewage disposal and its adoption by municipalities. From the report it would appear that action is being deferred pending the receipt of information regarding the fate of pathogenic germs in their passage through the septic tank.

The following are among the more important estimates prepared and considered by the Board:—

1. A detailed plan and estimate for an additional filter-bed for the Burdwan water-works.
2. A combined scheme for water-supply to all the riparian municipalities on both banks of the River Hooghly, contemplating a daily delivery of eight gallons of filtered water a head for a population of 285,000, at a capital cost of about £270,000 and an annual cost of £4,000, was prepared. This being considered too expensive, another scheme was drawn up under the orders of Government for the supply of unfiltered water to 17 of the towns at a cost of about £217,000. Both schemes are now before Government.
3. A scheme for the supply of unfiltered water to Wards I and II of the Narayangunge municipality at a cost of £11,934.

The opinion of the Board was requested on schemes for the drainage of Titaghar, English Bazar, Dinajpur, Monghyr, Baranagore, and Manicktolla.

The Manicktolla drainage project includes the complete surface drainage of the town at a cost of £31,800, and presents considerable difficulties as the main outfalls discharge into tidal water.

The Board also advised regarding schemes for the supply of filtered water to the Garden Reach municipality; for the extension of the Howrah water-supply; and for remodelling the Darjeeling water-supply; and dealt with a large number of miscellaneous references.

Assam.—The total income of the municipalities, towns, stations, and unions in Assam, excluding four small towns in the Surma Valley which have no separate income, was £14,942. The aggregate of the sums devoted to sanitation was £8,262, or 55·29 per cent. of the total income, as compared with 44·69 per cent. in the preceding year. On conservancy £4,864 was spent, or considerably more than half the total; on water-supplies £1,480; on drainage £730; while the balance was spent on vaccination (£84), markets and slaughter-houses (£575); and £470 on various sanitary improvements. The largest share of municipal income devoted to sanitation was 89·77 per cent. at Dhubri. The municipalities of Gauhati and Tezpur and the Habiganj union spent upwards of 65 per cent. of their incomes, while all the other bodies spent upwards of one-third, except municipality of Goalpara and the Golaghat union, which is at the bottom of the list with 24·68 per cent.

No work of capital importance was undertaken during the year, and most of the expenditure on new work was in connection with improvements to the water supplies.

Although papers were circulated to the members whenever this was thought necessary, the Sanitary Board held only one formal meeting during the year.

United Provinces of Agra and Oudh.—No details regarding municipal or district board income, or of the expenditure on sanitation, are furnished in the provincial report. It does not appear that any new project of importance was undertaken during the year, although something was done towards the improvement of existing works and schemes.

At Agra it was found that there was danger of pollution of the water-supply, by a village situated about a mile above the intake, and enquiries were in progress to ascertain if it was possible by the construction of a spur running into the bed of the river to effect a slight deviation of the current so as to avoid the village. Owing to the increase in the demand for water, an extra settling tank was constructed. At Cawnpore the drainage and sewerage scheme is still under contemplation; but the construction of main and low-level intercepting sewers has been commenced. A city improvement scheme, providing for widening the worst streets, improving thoroughfares, and constructing new streets, is under consideration. At Lucknow it is hoped that the new sewerage and drainage scheme, which is under consideration, will soon be begun. At Farrukhabad a

drainage scheme to cost £5,000 was being carried out. At Aligarh the construction of outfall drains for sullage was in progress. For Dehra Dun a detailed scheme for the improvement of surface drainage was prepared.

The great water-supply works continue to work well. The estimated consumption during the year in the different towns in gallons per head was as follows :—Benares 12·21 ; Lucknow 4·5 ; Cawnpore 10·9 ; Agra 8·3 ; Allahabad 9·6 ; Meerut 4 ; Dehra 7·5 ; Mussoorie 6·39, and Naini Tal 11·87. As compared with 1900, all show an increase except Benares and Meerut. In Benares the decrease is small, but in Meerut the consumption of water has fallen from 8 to 4 gallons a head. The reason for this is not clear, but the falling off is in the consumption outside the cantonment, within which the increase was nearly 34 per cent.

The Sanitary Board held five meetings during the year. They considered projects and estimates amounting to £48,300, of which the more important were the following :—

An estimate amounting to £2,310 for the purchase and erection of four new boilers and altering the boiler-house at the Agra water-works was recommended for sanction. An estimate (£160) for extending the Mussoorie water-supply was approved. Plans and estimates (£5,000) for improving the drainage of Farrukhabad, plans and estimates (£1,674) for improving the Ganda Nala, Cawnpore, and plans and estimates (£2,290) for the drainage of Muzaffarnagar were approved.

The Cawnpore drainage and sewerage scheme was discussed, and the estimates for the main and low-level sewers, amounting to £32,540, were recommended for sanction.

The reports of the working of the village Sanitation Act during the year were considered, and the Board noted with satisfaction that the attention paid to improving the sources of water-supply and to general sanitation in the villages to which the Act has been applied was well sustained.

Punjab.—The aggregate income of the municipal towns in the Punjab in 1901, including an opening balance of £73,130, was £387,310, and of this sum rather more than 20 per cent. was spent on sanitation ; on water-supplies £14,156 ; on drainage and sewerage £4,916 ; on conservancy £44,496 ; on the construction of latrines £800 ; and on paving and widening streets £2,818.

The amount derived from the sale of manure in the municipal towns, which had been declining in previous years, rose from £9,521 in 1899 to £10,812 in 1900, but owing to the transfer of certain towns to the North-West Frontier Province there is an apparent decline in 1901 to £10,032, including £2,670 obtained in Amritsar, £943 in Delhi, and £756 in Lahore.

The more important works completed were the following :—

The extension of the Delhi waterworks, comprising an inlet well and pumping station on the bank of the Jumna, with two settling tanks and six filter beds.

The Abbottabad drainage scheme was finished in June, and has worked satisfactorily.

The Fazilka drainage scheme, although completed, was not taken over by the Municipal Committee, because the working was not satisfactory. Proposals for the alteration of the drain at a cost of £267 were submitted to Government.

At Simla, the Saog reservoir and the lower gravitation line were finished, and the extension of the old gravitation line was completed. The sewerage system was extended and an installation for the experimental treatment of sewage was set up.

The following schemes were under consideration or were sanctioned : —

The estimate for the Amritsar water-supply scheme was sanctioned by the Government of India, and work, it was hoped, would be begun when a more suitable site for the supply wells had been approved.

The water-supply scheme for Lyallpur town and civil station and the drainage scheme for the town were sanctioned by the Local Government.

A project for the better drainage of the Simla bazar was prepared.

The extension of the Kalka water-supply and drainage scheme for Rawalpindi, Multan, and Ferozepur were considered.

The Sanitary Board met five times during the year, and the following were the principal subjects considered by them :—

(1) Rules for the guidance of the Board, of the Sanitary Engineer, and of local bodies were drafted and submitted to Government for approval.

(2) A drainage scheme for the town of Chunian was approved and sent to the Commissioner of Lahore for action.

(3) The Umballa extramural drainage project was approved and sent to the Commissioner of Delhi for action.

(4) A drainage scheme for Chiniot Road town was approved.

(5) and (6) The Lyallpur water-supply and drainage schemes were modified and approved.

(7) The Gujarat extramural drainage scheme, prepared by the Sanitary Engineer, was approved, and referred to the local authorities, in order to ascertain if they were prepared to meet the cost.

North-West Frontier Province.—The income of the municipal towns amounted to £43,234, including an opening balance of £10,957 and £1,148 derived from the sale of manure and street sweepings. The following sums aggregating £7,280 were spent on sanitation: on conservancy £4,074; on drainage and sewerage £1,062; on water-supply £1,933; and on the construction and repair of latrines £212.

No new work of capital importance was undertaken, although improvements in the drainage of Abbottabad and Peshawar were carried out. At Abbottabad arrangements are being made to obtain a supply of water from the Kakul wells as the existing supply is insufficient. The extension of the water-supply of Kohat and a scheme for the drainage of Dera Ismail Khan were under consideration.

Central Provinces.—The total income of the district headquarters' municipalities for the year 1900–01, excluding opening balances and certain receipts under special grants, &c., was £70,062, or £1,294 less than in the preceding year. Of the total income 33·29 per cent. was spent on original and recurring sanitary works, against 28·18 per cent. of the income in 1899–1900. The expenditure on new works was very small, both in the towns and in the districts, on account of the heavy expenses that had to be incurred on account of the famine. Considerable improvements were, however, effected in the drainage of some of the larger towns; the storage capacity of the Ambajheri reservoir at Nagpur was increased, and a new filter-bed was constructed near the river pumping-station of the Fraser water-works at Wardha.

The Sanitary Board met four times during the year in the districts of Jubbulpore, Narsinghpur, Hoshangabad and Nimar, and a good deal of work was carried out under their direction, chiefly the construction and repair of wells and the clearing of village sites.

Berar.—The estimated income of the twelve municipal towns in Berar in 1901 was £17,582, or £1,436 less than in 1900. Of the total, 36 per cent., or £6,439, were spent on sanitation, as compared with £8,483 in the preceding year. The sums spent on sanitary works by district boards amounted to £5,142, or £2,052 less than in 1900, the decrease being mainly under the heading water-supply in the districts of Amraoti and Akola.

The Sanitary Board met once at each district headquarters, the matter under consideration being the amount of practical effect given by local bodies to the suggestions of the Sanitary Commissioner recorded in previous years in his survey notes on towns and villages.

Madras.—No details regarding income or expenditure are furnished in the provincial report. The construction of the waterworks' extension and protective works at Trichinopoly, which were commenced in 1900, were still in progress during 1901, the extension to Worriur, one of the suburbs, being the only work of capital importance completed in the Presidency during the year. The Vizagapatam and Coconada water-works, begun in 1900, were also in course of construction, and a scheme for the water-supply of Ootacamund from the Tiger Hill reservoir was being carried out.

District medical and sanitary officers inspected 424 towns and villages, and forwarded copies of their reports to the Sanitary Commissioner and to the local bodies concerned. When the expenditure required on the alterations advised is trivial, it appears that action is generally taken, and in this way valuable improvements in respect of village water-supplies, conservancy, and the sanitation of schools have been effected; but the Sanitary Commissioner recommends that a definite percentage of the available funds should be set aside for expenditure on sanitation.

Progress in sewage farming, sewage filtration, and the employment of town sweepings and night-soil for agricultural purposes continues to be made, and Government sanctioned a series of experiments on the use of sewage filtrates as fertilisers.

During the year the Sanitary Board scrutinized the plans and estimates of 85 sanitary works, of which 38 were for municipalities, 43 for local fund boards, three for the Collector of Madura, and one for the Collector of Salem, the aggregate estimated cost of the projects being £96,000.

The following were among the projects sanctioned by Government on the recommendation of the Board :—

(1) The construction of the Tiger Hill reservoir in connection with the Ootacamund water-supply.

(2) Improvements in the Ootacamund market, £1,337.

(3) Closing the wells at Calicut within fifty yards of the Kannanparamba burial ground.

The following are among the schemes examined and laid before Government :—

(1) The Erode water-supply, Cauvery scheme, £6,867.

(2) Amended water-supply scheme for Kumbakonam, £27,000.

(3) The Ongole water-supply, £8,000.

(4) Sinking artesian wells at Ellore, £1,460

(5) Augmenting the water-supply of Adoni, £1,074.

roposals for many more schemes were received and considered by the Board, but few of them were in a sufficiently advanced state to admit of estimates being prepared.

Coorg.—Particulars regarding the revenue and expenditure on sanitation in the towns and districts of Coorg are not furnished in the report ; but, beyond the construction of a low-level cistern in connection with the waterworks at Mercara and improvement to the surface drainage of the town, no expenditure on sanitation calling for special remark was incurred.

The Sanitary Board met twice during the year, but no business of importance was transacted by them.

Bombay.—Excluding the Presidency town, there were 165 municipalities in Bombay, and their aggregate income in 1900–1901, including opening balances, was £479,894. The amount spent on conservancy, drainage, and water-supply was £95,168, or about 19·83 per cent. of the income. The total income of the 23 district and 207 taluka local boards was £272,325, and the expenditure on water-supply and drainage was £11,566, or about 4·24 per cent. of the income.

It is explained that the presence of plague and famine deterred local bodies from initiating any sanitary scheme of importance.

The number of meetings of the Sanitary Board is not reported, but the following are the principal matters which occupied their attention during the year :—

Kaira.—A project was prepared by the Sanitary Engineer for the supply of water from a well situated about a mile from the town. The estimated cost is £6,554 for the supply and distribution of 100,000 gallons a day.

Mehmedabad.—A somewhat similar water-supply project to cost £5,672 was prepared by the Sanitary Engineer.

Poona.—The drainage and water-supply scheme which was estimated to cost £293,000 was rejected on account of the excessive cost, and a modified partial scheme for drainage to cost £71,810 was prepared and was being considered by the municipality.

Plans and estimates amounting to £3,018 for an experimental sewage farm at Manjri were prepared. Fifteen acres of land were acquired and fenced in, and a septic tank and bacteria beds were constructed.

Ahmednagar.—The Sanitary Engineer checked the plans and estimates amounting to £15,310 for the Nagabhai and Kapurwadi water-supply scheme for the city, and they were sanctioned by Government.

Burma.—The addition in 1901 of Allanmyo to the municipal towns of Burma raised their number to 42. The aggregate income of the year, including opening balances amounting to £121,600, was £440,226, or about £130,000 more than in the preceding year.

The proportion of income devoted to sanitation in 1900 was 55 per cent., and this was reduced in 1901 to 35 per cent., including 13 per cent. on conservancy, 9 per cent. on water-supply, and 6 per cent. on drainage.

It is stated that a number of municipalities have important schemes on hand which they are unable to carry out owing to want of funds, and that the question of rendering assistance from provincial revenues is receiving the attention of the Local Government.

At Rangoon the scheme for constructing a lake reservoir at Thamaing had to be given up owing to the great expense involved in acquiring the necessary land. The Hlawga project, for which a survey was made and an estimate amounting to £260,000 was prepared in 1893–94, was brought forward and sanctioned. The demarcation of the land for the reservoir, which is to hold 13,950 millions of gallons, was begun in December.

At Moulmein the cost of the scheme which provides for an impounding reservoir on the Taungwaing hills, about five miles south-east of the town, was revised and work was begun in December. The scheme provides for a reservoir to hold 648 million gallons, at a height of 45 feet above the town, throughout which the water will be carried in pipes.

At Akyab the preliminary scheme was revised at the request of the municipality, and a partial supply preliminary scheme was submitted for approval.

At Myingyan two complete gravitation schemes were prepared. The first is for the construction of an impounding reservoir to store 464 million gallons, 121 feet above the general level of the town, at Chezi, six miles to the south-east of the town. The second is for a reservoir to hold 486 million gallons, 100 feet above the level of the town, at Kyaukyan, two miles to the east of the town. The adoption of the first scheme has been recommended.

At Minbu a project for water-supply from a well in the bed of the Sabwet *chaung*, about two miles from the town, whence the water will be pumped to a distributing reservoir on a hill half-way to the town, has been proposed.

Well schemes were also proposed for Yamethin and Letpadan.

No particulars of the Sanitary Board's proceedings are given in the provincial report.

General Remarks.

Red Sea Pilgrim Traffic.—In view of the stringent measures of quarantine imposed by the Turkish Government, and the inconvenience likely to be experienced by Indian pilgrims in Arabia, the Government of India warned intending pilgrims that they would be well advised to defer their visit to the Hejaz. Arrangements were, however, made at Karachi and Chittagong for the embarkation of pilgrims from areas uninfected by plague; but persons permanently or temporarily resident in any of the infected places were forbidden to embark. At Karachi and Chittagong observation camps were established, where the pilgrims were detained and their clothing and other effects thoroughly disinfected before embarkation. At these observation camps alone could tickets for the voyage be purchased.

Four vessels left Chittagong carrying 2,210 pilgrims. Among them some cases of small-pox were detected at Aden, where they were landed and isolated; and the vessels, after disinfection, were allowed to go on to Cameran. At Cameran itself five cases of small-pox developed, but the precautions which were taken prevented the spread of the disease. Still, in one of the ships from India several cases of small-pox were found on arrival at Jeddah, but the disease soon disappeared.

At Karachi plague re-appeared early in 1901, so that only two vessels, carrying 669 pilgrims, left that port during the season.

Indian pilgrims to the number of 568 arrived at Jeddah from Suakim, Suez, Aden, and other ports, and about 50 overland through Persia and Arabia.

Except for the occurrence of small-pox the health of the pilgrims from India was good.

At Cameran 18,315 pilgrims of various nationalities underwent quarantine; ten days in the cases of pilgrims from India, the Persian Gulf, and the Arabian Coast, and five days in the cases of pilgrims from Java and the Straits Settlements. The health of the

pilgrims at Cameran is stated to have been excellent, and only 12 died, including five Bengalis, all of whom were old people. The scheme for the re-construction of the camps at Cameran does not appear to have been efficiently carried out, and it is stated that, although much money has been spent, very little has been accomplished. The hospitals in the camps are reported to be very imperfect.

The health of the pilgrims in the Hejaz was very good, and as neither cholera nor plague was reported to be present, the quarantine restrictions imposed upon pilgrims returning to Egypt were very slight.

During 1901 the number of pilgrims who landed in Bombay was 1,290. They were conveyed in many vessels, the largest number in one ship being 437 on the S.S. *Hosseinee* and 297 on S.S. *Assyria*. On three of the vessels bringing returning pilgrims to Bombay single cases of small-pox occurred ; one case was landed at Aden, another at Karachi, and the third at Bombay. Disinfection was carried out at both Aden and Karachi. The baggage of all the 1,290 pilgrims who landed at Bombay was thoroughly disinfected ; such pilgrims as were returning up country were not allowed to enter the town, but were sent straight from the disinfecting sheds to the railway station, and thence by train, at Government expense, to their homes.

Two steamers, the *Akbar* and the *Mahammadi*, arrived at Diamond Harbour on the 7th and 10th of May respectively. The *Akbar* had on board 434 pilgrims, but there had been 16 deaths during the voyage, and three sick had to be admitted to hospital on arrival. The *Mahammadi* had on board 402 pilgrims, all of whom were in good health, but there had been 20 deaths on the voyage. The diseases from which the pilgrims died on the ships were, for the most part, such as are incidental to old age and poverty, and did not include any of the infectious diseases.

It appears that many Indian pilgrims proceed to Hejaz insufficiently provided with money, and when the time comes for their return to India they have to depend upon charity not only for their return passage, but for money to purchase food for them while they are waiting for a steamer. In this connection the British Vice-Consul writes :—

"The Indians are still under the impression that a sum of three hundred rupees is quite sufficient to carry a pilgrim from India to the Hejaz and back, but they are quite mistaken. The old times have changed when everything used to be cheap * * * * and the journey costs now twice the money which used to be sufficient formerly. According to my estimate an Indian pilgrim ought to provide himself with Rs. 500 at least before leaving for the Hejaz."

He also advises Indian pilgrims to deposit about Rs. 80 at the British Vice-Consulate on their arrival at Jeddah to cover the cost of the return journey.

Malaria.—Important contributions to our knowledge of malaria have resulted from the labours of Drs. Stephens and Christophers, missioners sent out by the Royal Society, and of Captain S. P. James, I.M.S., who was deputed by the Government of India to assist them. After visiting various places in India, the Commissioners selected the cantonment of Mian Mir for a series of test experiments. These experiments were begun by Drs. Stephens and Christophers, and on their departure from India were completed by Captain James.

A malarial survey of the cantonment of Mian Mir had been made in the latter part of 1901, when it was found that the reputation of Mian Mir as one of the most malarious cantonments in India was thoroughly well deserved. For this reason, and because of the comparatively small rainfall during the rainy season, Mian Mir was chosen for a series of experiments on a large scale regarding the value of certain measures which may be taken against malaria. Much has been written regarding the value of particular remedies, but it has not been generally realised that there is probably no one infallible remedy, that physical conditions must be taken into consideration, and that what may be an effective remedy in one place may be nearly useless in another.

The principal object of the Royal Society's Commission was the problem of mosquito destruction, and after carefully considering the conditions in Mian Mir, it was thought that this method of prophylaxis would offer the best chance of success. At the same time it was decided not to neglect other measures, such as the careful administration of quinine, or the removal to a safe distance from the barracks of any bazar proved to be a source of infection. The first matter to be considered was how the success of a remedy could be estimated. The general opinion of the inhabitants was obviously too vague a measure, while any estimation of the comparative abundance of adult *anopheles* mosquitoes alone would be too largely dependent upon the skill of an individual observer.

It was decided that the degree of success attained could be best gauged by taking several indications into consideration.

1. The apparent effect upon the number of larvæ.

2. The apparent effect upon the number of adult *anopheles* mosquitoes.

3. The effect upon the amount of malarial disease as determined by (*a*) the hospital admission-rate ; (*b*) the percentage of the men found infected ; and (*c*) the percentage of children under 10 years of age with malarial parasites in their blood (endemic index). This last test, the endemic index, is certainly the one on which the most reliance can be placed.

The cantonment of Mian Mir covers so great an area that it was practically impossible to carry out operations in every part of it at the same time, and it was therefore resolved in the first instance to carry on experiments in the lines of the Royal Field Artillery, situated in the most malarious part of the cantonment. The malarial survey of these lines had shown that there were four chief sources of infection for mosquitoes ; namely, the syce lines of the 51st Field Battery situated within fifty yards of the barracks ; the syce lines of the 54th Field Battery situated within a quarter of a mile of the barracks : the hospital followers' lines within one hundred yards of the barracks ; and the Royal Artillery bazar within a quarter of a mile. The endemic index of those places varied from 30 to 60 per cent.

Six species of *anopheles* mosquitoes were found in the lines and bazar, two of them, *A. Rossii* and *A. Culicifacies*, being exceedingly numerous.

It was found that the chief, if not the only, carrier of malarial infection in Mian Mir is the *A. Culicifacies*, the principal breeding places of which are the irrigation watercourses which pass around and through the lines in all directions. The water in these channels is sheltered and impeded in its flow by grass and weeds growing at the edges, and it was found that if the grass and weeds were removed, so that the water flowed along freely at at the sides as well as in the middle of the channel, the numbers of larvæ were greatly reduced.* It was hoped, therefore, that constant cleaning of the channels for months together would produce a lasting effect upon the number of *anopheles* moquitoes, and the principal operations were directed to this end. It was also proposed to line one of the watercourses with bricks and plaster in order to ascertain the effect of such a measure upon the numbers of larvæ in that watercourse. The puddles that would form during the rains were to be filled in. One or more of the regimental bazars was to be moved to a considerable distance from the lines, and quinine was to be issued prophylactically to the troops.

Operations were begun at the end of March under the direction of Captain James with the help of a hospital assistant. Twenty coolies under a headman of the Canal Department were set to work to clear away the grass and weeds from the irrigation channels, to fill up small bays and backwaters, to deepen the channels in places and in every way to improve the flow of water. By the end of April all the water courses had been treated in this way, and the men were free to recommence operations, going over every part more thoroughly and carefully than before, and smoothing the sides of the channels by plastering them with clay. Such operations were constantly repeated, two men being eventually told off to each watercourse to keep it clear, not only of vegetation at the sides, but of floating leaves which afforded shelter to larvæ.

Great practical difficulties were encountered. Many of the watercourses end in the pool of a Persian-wheel, so that, except for about three hours daily when the wheel is working, the water is stagnant. An attempt was made to deal with such watercourses by thoroughly cleaning and drying them once in every ten days ; but the great cost of doing this, and the fact that, in the hot weather, *anopheles* mosquitoes develop from the egg to the adult in less than ten days, render such a measure impracticable. Some of these watercourses were treated with kerosine oil, and this was temporarily successful, but care is necessary to prevent the oil being drawn up by the Persian-wheel and run on to the fields.

One of the irrigation watercourses, about a half a mile in length, running through the middle of the lines in front of the barracks and hospital, which was an exceedingly abundant source of *anopheles* mosquitoes, was lined with bricks plastered with cement.

---

* Compare a valuable paper, "A Preliminary Report of Observations of the habits of Anopheles," by Lieut.-Colonel R. N. Campbell, M.B., I.M.S., and U. N. Brahmachari, M.B., *Indian Medical Gazette*, January, 1902.

This work was begun in May and completed in July, and has resulted in a great reduction in the numbers of larvæ in the watercourse.

When the rains began the difficulty attending the experiments increased. The surface of the land on which Mian Mir is situated is flat, and though the soil is sandy the subsoil is impervious. The rain which falls between May and October is generally distributed in frequent showers. Every heavy shower floods large patches of land and fills the numerous cuttings, which having no fall can scarcely be called drains, the water dries under the hot sun that follows the dispersal of the rain-clouds, but before the larger collections of water are dried another shower fills them anew. With the first rainfall in May additional men were employed to drain away surface collections of water and to fill up a number of the deeper pools. About 250 pools of various sizes and two large tanks were filled in.

It had been found in October, 1901, that 60 per cent. of the children of the syces in the lines situated within fifty yards of the barracks were infected with malaria. On the 18th of July, 1902, these lines were removed, the syces and their families being accommodated in tents half a mile away from the barracks pending the buildings of new lines.

In the other syce lines and in the lines of the hospital followers the systematic treatment of all children with quinine was carried out. It was found that after the first few doses most of the children took the quinine readily, and that even quite small children suffered no ill effect from a dose of ten grains given on several consecutive days. The natives themselves have appreciated the good results of this treatment as evidenced by the greatly improved health of their children. Another prophylactic measure was the systematic administration of quinine to the troops, which was effectively carried out by means of quinine parades twice a week on consecutive days from the 18th of April.

The operations directed to the destruction of larvæ certainly brought about a reduction in the numbers of adult *anopheles* mosquitoes, but in spite of the checks upon their breeding adult *A. culicifacies* and *A. Rossii* could be readily found in the houses from July to November. The numbers were, however, less in that part of the cantonment in which the operations were carried out than elsewhere. But it is evident that the problem of materially reducing the number of *anopheles* mosquitoes in Mian Mir is a very difficult one, mainly because the majority of the breeding places cannot be permanently done away with, and it seems to be doubtful whether any operations short of this will produce a very marked reduction in the number of mosquitoes.

The removal of the syce lines from a site about 140 yards from an irrigation watercourse to tents pitched three-quarters of a mile away from the nearest watercourse and 600 yards distant from the nearest pool produced very striking results. No *anopheles* mosquitoes were to be found in the tents in September and October. Otherwise, except that they were more exposed to the sun and rain and vicissitudes of temperature, the general conditions of life of the syces and their families were unchanged. The percentage of infected children was reduced from 56·5 in October 1901 to 4 in October, 1902; the number of children with enlarged spleens was reduced from 75 per cent. in April, 1902, to 60 per cent. in October, 1902; and not a single case of fever occurred among the adults throughout the season.

The treatment of the children in the other syce lines was attended with favourable results so far as the children were concerned, and there was said to be a remarkable reduction in the number of cases of malarial fever among their fathers.

The effects on the troops are less easy to gauge. In the first place, the year was an unusually healthy one; in the second, the statistics were deranged by the arrival in the station of a second British infantry regiment in October, and the departure in the end of the same month of both batteries of Royal Artillery to Delhi, men attacked by malarial fever occurring on the line of march being sent back to hospital in Mian Mir; and in the third place, there was much greater care displayed by medical officers in the diagnosis of malarial fever, the tendency being to return doubtful cases under some other heading. Taking all these factors into consideration the results seem to show that the operations were successful in diminishing the incidence of malarial fever.*

---

* Full particulars will be found in a forthcoming number of the *Scientific Memoirs*: a Report of the Anti-Malarial Operations at Mian Mir (1901–3), by Captain S. P. James, I.M.S.

With a view to instructing Assistant Surgeons and others who might not have convenient access to larger works, a brief statement of the results of recent researches into the causation and prevention of malarial fevers was drawn up by Captain James. Nearly five thousand copies were circulated, and after the edition was exhausted there remained a demand for more copies. To meet this a new edition has been prepared and is in the press. The text has been revised, illustrations have been added and the scope of the work has been enlarged so as to make it a convenient introduction to the study of malaria.

Tuberculosis in India.—Increasing attention has in recent years been devoted to the occurrence in India of tubercular diseases, with a result, not unknown in similar cases, that what was generally thought to be rare has been found to be common; and the remark is frequently seen, "the more tubercle is looked for, the more often it is found." The consequence of this is that the belief is becoming prevalent that tubercular diseases are not only of frequent occurrence in India, but that they are rapidly increasing in frequency.

How far this is true it is not possible to say, but granted the greater attention given to the subject and the possibility that implicit reliance ought not to be placed upon the positive result of the microscopical examination of the sputum, it does not appear that the figures obtained from army hospitals and from prisons furnish evidence of any considerable increase of tubercular diseases in the country generally.

In the following statement the admission and death rates per 1,000 of strength among European and native troops and among convicts in Indian prisons are given.

The figures for the years 1891 to 1894, inclusive, are not precisely the same as those given in the statistical tables appended to this report for the following reason :—In 1895 the *post-mortem* records of all cases of pneumonic phthisis were very carefully examined, when it was found that nearly all these cases were associated with the presence of tubercle, and the returns were changed accordingly. Since 1895 no death has been entered in the statistics as due to pneumonic phthisis, unless the medical officer reporting it, after special reference, has reaffirmed his belief that tubercle was not present. Such cases are rare.

For purposes of comparison all cases of pneumonic phthisis which were recorded prior to 1895 have been included as cases of tubercle of the lungs.

Year.	European Troops.		Native Troops.		Jails of India (excluding Andamans).	
	Admission per 1,000.	Deaths per 1,000.	Admission per 1,000.	Deaths per 1,000.	Admission for 1,000.	Deaths for 1,000.

Among European troops there has apparently been no increase in recent years in the ratios of admissions and deaths from tubercle of the lungs. The high admission-rates in

1895–97 were due to the prevalence of phthisis among the men of a recently arrived regiment recruited in a mining district. The invaliding statistics do not show any increase either. Exceptionally small numbers were invalided in 1893 and 1899 (·80 and ·75 per 1,000 respectively), but in the other years the millesimal ratios have fluctuated between 1·10 in 1891 and 1·76 in 1896. Among native troops, although the death-rates in the years 1899–1901 are higher than in any other three consecutive years, the rate in 1897 is higher than in any other year of the eleven except 1901. There is, however, a distinct rise in the admission-rates from 1898 onwards.

In this Report for 1899 it was shown that as the ratios of deaths ascribed to anæmia and debility among prisoners fell so the ratios of deaths from tubercle rose. It would appear that there has been a similar change in the regimental hospitals. Between 1891 and 1897 the lowest admission-rate for anæmia was 4·4 per 1,000 in 1895 and in 1896, while the lowest death-rate was ·12 in 1894. In 1897 the admission-rate fell to 3·5 and the death-rate to ·06. The anæmia admission-rates since have all been low, except in 1901, when the rate rose to 4 per 1,000; and the death-rates have remained at ·06, except in 1899, when the rate was only ·04. Early in 1897 the revised Nomenclature of Diseases, in which it is directed that when the cause of anæmia is known the case should be returned under the head of the primary disease, was taken into use; and the increase in the proportion of cases of tubercle of the lung is partially explained by the decrease in the proportion of cases returned as anæmia without special reference to the cause of the condition. The fact that the fall in the ratio of anæmia cases took place before the rise in the ratio of cases of tubercle of the lungs may possibly be explained by the peculiar conditions of 1897, when a large part of the army was on field service.

Among prisoners there was a considerable rise in the admission-rates for tubercle of the lung in 1893, and another in 1898, while the death-rates have gradually risen, and from 1899 inclusive have been over 3 per 1,000. The explanation of the rise of the rates among prisoners is not a simple matter, because so many factors exercise a profound influence on their health. A malarious year, for instance, will greatly add to the number of cases of anæmia. A famine year may be expected to add to the number of cases both of anæmia and tubercle, not alone because the classes from among whom the vast majority of prisoners are drawn are insufficiently fed, but because the increase of crime causes the jails to be overcrowded. Again, while the watchful care of the prisoners' health in many of the central jails could hardly be improved, the statistics receive contributions from small jails in outlying places where the medical skill is not always of the highest order.

The early years of the decennium were very malarious, and cases of anæmia and debility were very common, so that it could not be expected that the growing admission-rates for tubercle of the lung would be exactly balanced by declining admission-rates for anæmia. The years 1897 and 1900 were marked by terrible famines, and the condition of the people and of the jails favoured the development of both anæmia and tubercle. In 1898, however, there was a great fall in the admission-rate for anæmia, and the rates have not again risen.

Although the ratios of deaths ascribed to anæmia have fallen, their fall is not equal to the rise in the ratios of deaths from tubercle of the lungs. If, however, the death-rates from tubercle of the lungs and anæmia are taken together, the increase in the combined death-rates is not marked, and may be explained, at any rate for the most part, by the effects of the famine of 1900. There is, however, another heading under which deaths are returned which must be taken into account—debility and old age; and if the combined death-rates from tubercle of the lungs, anæmia, debility, and old age during the eleven years are compared, it will be found that the death-rates were exceptionally high in 1894 (an unhealthy year) and in 1897 (famine) and 1900 (famine), but no progressive increase is discernible. The tendency, then, has been for the tubercle rates to rise at the expense of the anæmia and debility rates; but as the hygienic condition of many of the jails has been improved, the rates under the latter heading should have fallen irrespective of the greater precision of diagnosis, so that it may be that tubercle has actually increased among the jail population. It certainly is not decreasing, and the death-rate from tubercle of the lungs is higher among Indian prisoners than it is among the English population at any age period.*

* Registrar-General's Report, 1900, page xxx.

The following statement shows the relation of tubercle of the lungs to anæmia and debility in the different jail administrations during 1901 :—

It is not yet possible to form any accurate idea of the amount and distribution of tubercular disease among the general population of India, as our registration returns, although they will in future include respiratory diseases, take no account of phthisis. But in the great seaports registration is more advanced, and the following figures compiled from the weekly Port Health reports, when compared with the figures recorded in London, are sufficiently remarkable :—

	Mortality per 1,000.		
	Total.	Excluding Plague.	Phthisis.
London (Registration County), 1900*	18·743	...	1·718
Calcutta, 1901†	37·7	28·4	1·2
Bombay, 1901†	75·5	51·6	8·3

* Registrar-General's Report, 1900, page cviii.
† Excluding one week for which returns not available.

In both towns and particularly in Bombay deaths from plague may be returned as deaths from phthisis, but, even if this is largely the case, the death-rate attributed to phthisis is very high, and it is satisfactory to know that special measures to combat the disease are being taken.

In connection with the Resolutions of the General Meeting of the British Congress on Tuberculosis, the Government of India took the opportunity to suggest to all local governments and administrations that leaflets, containing brief directions for the avoidance of danger to their neighbours, should be given at all public dispensaries and

hospitals to patients suffering from tubercular phthisis ; that suitable action in regard to the inspection of articles of food and drink should be taken in municipal towns ; that arrangements should be gradually made in all jails, where such do not already exist, for the isolation and treatment in the open air of phthisical cases ; and that the special attention of Inspectors under the Indian Factories Act should be drawn to the measures that can be taken under the Act to secure the absence of overcrowding, the provision of good ventilation, and the observance of cleanliness.

Pasteur Institute of India.—Excellent work continues to be done at the Pasteur Institute, Kasauli, under the direction of Major D. Semple, M.D., R.A., M.C. During the year ending 8th August, 1902, 543 persons who had been bitten by rabid animals were treated, as compared with 321 treated during the previous year.

The following tables exhibit the results among Europeans and natives respectively :—

The tables do not include twenty persons who presented themselves for treatment, but were found not to require it, nor do they include two patients (natives) who developed hydrophobia during the treatment, and four persons (one European and three natives) who were seized with hydrophobia within fifteen days after the last inoculation.

The results of the treatment of Europeans are perfect. The failures among natives are attributed to the following causes :—

1. Natives, owing to their scanty clothing, were generally more severely bitten than Europeans.

2. Many wasted valuable time before going to the institute for treatment.

3. In only a few of the cases had the wounds been cauterised early or efficiently; and in a considerable number of the cases the wounds had been neglected and were suppurating on arrival at the institute.

4. A large number were bitten by jackals.

The greater danger of the jackal's bite is illustrated by the fact that most of the casualties during the year occurred among a batch of 35 persons treated for jackal bites in August, 1901. These cases were treated in the ordinary way, but over 11 per cent. died. Since then, persons bitten by jackals have been treated by a more intensive method than those bitten by dogs, and out of 64 persons bitten by jackals treated in this way not one has died.

Major Semple urges the necessity for the immediate "first aid" treatment of all bites. He considers pure carbolic acid to be the best caustic, because it penetrates into all the crevices of the wound, without causing excessive pain. It should be thoroughly swabbed into the wound and then the wound should be washed with water. Failing carbolic acid, other caustics may be used, or an antiseptic solution or pure water. The object is to remove as much as possible of the poison from the wound and to destroy *in situ* what cannot be removed.

Major Semple deprecates the sucking of the wound, on account of the danger of inoculating the lips or mouth; and excision, on account of the danger of carrying the poison to the larger wound made by the knife. He also warns all persons bitten by rabid dogs of the great danger involved in delaying the commencement of the antirabic treatment.

In addition to the antirabic treatment, much general bacteriological work was carried out at the laboratory in connection with the diagnosis of enteric fever, Malta fever, malarial fever, plague, tubercle, diphtheria, tumours, &c.

Antityphoid vaccine for 4,000 cases was prepared and sent out.

Samples of brain and spinal cord of suspected animals to the number of 106 were tested, and in 80 positive results were obtained.

The preparation of antivenene was commenced, and the serum will soon be ready for issue.

Researches in connection with the improvement of the antirabic treatment especially with a view to dealing successfully with late cases were undertaken.

Investigations into the nature of surra, with the object of obtaining a curative remedy were carried out.

"Anthrax vaccine has been prepared and can now be sent to any part of India when required. The preparation of this vaccine necessitated a prolonged series of experiments in order to obtain cultures of anthrax bacilli of the requisite degree of attenuation. Ponies and sheep inoculated with this vaccine have withstood the subsequent inoculation of virulent anthrax taken direct from the spleen of a horse immediately after death from anthrax."

Lathyrism.—The apparently increasing prevalence among the people of the Central Provinces, chiefly in the districts of Saugor, Damoh, Hoshangabad, Jubbulpore, and Bilaspur, of a form of paralysis believed to be due to eating the seeds of a vetchling (*Lathyrus sativus*) known locally as *teora*, has led to a special enquiry, the conduct of which has been entrusted to Major Andrew Buchanan, I.M.S. It may be expected that this investigation will settle the vexed question of the cause of lathyrism and suggest practicable measures for its prevention.

Cerebro-spinal meningitis.—Among prisoners in Indian jails in 1902 there were 104 deaths ascribed to cerebro-spinal meningitis. Fatal cases occurred in every month of the year except July, the largest numbers of deaths occurring in February and March, 21 and 24 respectively. Cases occurred in six provinces, the Punjab heading the list with

41 (maximum monthly number 12, in May) closely followed by Bombay with 37 (maximum number 14, in March). Ten deaths occurred in the United Provinces, nine in Bengal, five in the Central Provinces and two in Burma. There can be little doubt that the disease was widely spread among the general population of many of the provinces. As the subject was one that called for special investigation an officer was appointed to carry out an enquiry into the etiology of the disease as it occurs in India. Captain Robertson Milne has been selected for this purpose.

Scientific Memoirs.—In 1884 the publication of the Scientific Memoirs by Medical Officers of the Army of India was begun for the purpose of affording a convenient medium for the publication of selected original papers on scientific subjects which it had been the custom to include in this report. Twelve parts of the Scientific Memoirs have been published, the last in 1901. It was found in practice that the publication of such papers at certain intervals presented serious disadvantages ; on the one hand, the supply of suitable contributions was exceedingly irregular, and on the other important papers had to be held over until sufficient matter to fill a volume accumulated.

To obviate those disadvantages it was decided to publish papers separately as soon after their completion as possible ; and the opportunity was taken, while retaining the old name of the series, to enlarge the title so that papers by all officers of the Medical and Sanitary Departments of the Government of India might be included. At the same time the arrangements for the distribution of the numbers of the series were revised, and copies are now very widely distributed, not only in India and in Great Britain, but to most of the universities and to many of the more important scientific libraries throughout the world.

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER FOR MADRAS FOR 1901.

(*Lieutenant-Colonel W. G. King, C.I.E., I.M.S.*)

General Population.

The population of the Presidency, according to the Census of 1901, was 38,623,066. The European and Eurasian population included in this total amounted to 40,231. The "natural increase" since last census amounted to 2,572,646, against 4,879,894 in the former intercensal period. The intercensal rate of increase for the Presidency, excluding feudatory States, was 6·99 per 1,000, but if the districts that had been specially subjected to famine and scarcity during the period be excluded, namely, Kurnool, Cuddapah, Bellary, Ganjám, Gódávari, Kistna, Vizagapatam, Anantapur, Nellore, and North Arcot, the rate of increase has been 7·24 per 1,000. Cooly emigrants during the year exceeded immigrants by 4,849. The population under registration during the year was 37,315,611. In all municipal areas registration of births and deaths was compulsory, and also in 441 against 400 villages in the previous year, under Act III of 1899. Owing to the absence of the enforcement of the Village Proprietary Act, it is still impossible to secure correct statistics from rural areas under zemindars. The method of inspection of registration records stated in former reports continues. At the suggestion of the Government of India, registration in rural areas under the heads "plague" and "respiratory disease" has been required. The forms employed in rural areas are under discussion. In reply to enquiries as to how many District Medical and Sanitary Officers have arranged to carry out my suggestion that Municipal Registrars should be trained in respect to medical terminology, the majority have reported that action has been taken. 87 prosecutions were undertaken by Municipal Councils for failure to comply with legal requirements as to compulsory registration.

Births in Districts.—The total births reported during the year in the whole Presidency were 935,749, against 1,049,199 in the year 1900—a decrease of 113,450. The birth-rate per 1,000, therefore, reckoned upon the population according to the census of 1901 was 25·1, or a decrease of 6·7 per 1,000 when compared with the previous year. This indicates a very heavy fall in fecundity, even were allowance made for factors recognized as tending to the securing of imperfect statistics. One source of error is, however, at once apparent in this calculation. It has already been pointed out by me (and in this I have been supported by the Madras Government) that reckoning upon a census population year by year without allowing for the intercensal rate of increase, permits of an appearance of improvement in registration results that may not exist in fact. But, on the next census figures being available, a sudden drop in this improvement must occur, to be duly resumed in the succeeding years. This would at all times be avoided by use of "estimated populations." This having been forbidden, I at least may appeal to the fact that, if the 1901 births be reckoned upon the 1891 census, as was the case in 1900, the birth rate results are by no means so appalling; the rate then becomes 28·3 per 1,000, and shows, by comparison with 1900, a fall of 3 5 per 1,000. But a fall in the total birth-rate of the Presidency has not been unexpected in that, as shown by Mr. Stuart in the Census Report for 1891, the rate of increase in the intercensal period dealt with by him was abnormal, as a result of the age constitution of the people following the mortality of adults in the 1876–77 famine. This factor must show increasing power for some years to come; but the sudden fall during the year under review cannot be fully thus explained. It cannot be ascribed to laxity in registration at a period when compulsory registration has been advanced in many areas, and the endeavour to secure better registration has been evident throughout the Presidency. Moreover, such an argument would

assume that unusual carelessness has been exhibited in 21 out of 22 districts. I can discover no religious or other reason to believe that marriages were not carried out as usual during the year, or in that preceding it. Hence allowing the factor of changing age constitution of the population full weight, the result must, in great part, be ascribed to the well known physiological influence of high prices of food upon fecundity. In accepting this interpretation it must be remembered that the strain of high prices of food has acted upon certain classes of the population for successive years.

In scrutinizing the birth-rates of the various districts, to secure their just appreciation it would be necessary to compare results, as I have done, in considering the whole population of the Presidency, in the preceding paragraph ; but as this would be inappropriate, it will, I hope, be remembered that the decrease of the birth-rate is not so great as the figures would convey, and that they are of utility only in making comparisons, seeing that the error is common to the whole. Further explanation is necessary as to the rates in the case of Ganjám and Madura. Both these districts include large zemindari tracts. It has not been possible to obtain from the Collectors statistics for these, nor has it been possible, in communication with the Superintendent of the Census, to exclude the populations concerned ; hence, the total births reported from tracts other than zemindari have been applied to the total population—a very weak method of calculation, but the only one feasible. If these two areas be excluded, it is found the more notable diminution of birth-rates, when compared with the preceding year, occurred in Chingleput (13·6), North Arcot (9·8), Madras (9·0), Kistna (8·6) and Kurnool (7·5).*

Deaths in Districts.—Were the decrease of birth-rate explainable on the grounds of mere cessation of marriages, as a result of precaution in view of high prices, the death-rate would show a diminution, by reason of less number of deaths of infants ; but where the impress has been upon the fecundity of a population as a result of high prices of food-grains, an increase of the death-rate may be expected to occur if the strain has been severe, notwithstanding the less infantile rate. It is, however, obvious that whilst this factor was sufficiently powerful to depress the physiological functions, it has not been sufficient to sensibly increase the total mortality. The total deaths during the year were 796,140, or an increase of 25,281 when compared with the previous year. Reckoned upon the census population of 1901, the total death-rate was 21·3 per 1,000. Of the total deaths no less than 81,370 were due to cholera, whilst only 3,226 in excess of the number of the previous year were due to "diarrhœa and dysentery"—the diseases *par excellence* attending privation. Under all other heads of registration except plague (3,035 cases) there was a diminution of mortality. The total death-rate of infants below one year of age was 166·2 per 1,000 of the registered births, against 164·9 per 1,000 in the previous year. The death-rate of male infants was 174·6, against 157·5 per 1,000 of females. In no district except the Nilgiris did the mortality of female infants exceed that of males. In the case of Malabar, the total registered infantile death-rate was 98·9 per 1,000 of births. This is in complete contrast with results in other districts of the Presidency, and must be ascribed to failure to register deaths of infants, and to the long established custom of that area of burying infants within private premises. The necessity for care in the registration of births and deaths of infants was particularly urged by me upon all authorities responsible, in June 1899. Having regard to the scattered condition of houses in villages in Malabar, however, better results can be expected only as a consequence of steady insistence through a series of years.

Births in Municipalities.—The population under municipal administration amounts to 2,406,455, according to the Census of 1901. The total births (78,554) yield a birth-rate of 32·6 per 1,000, against 38·5 per 1,000 in 1900. Reckoned upon the census population of 1891, the rate was 36·2. There was a decrease of 4,490 in total births registered in municipalities when compared with the total of the previous year ; this occurred in 44 towns of a total of 61. That the town population of the Presidency should have been less influenced than the rural as to fecundity by the high price of food-grains, seems to support the view that the pressure was chiefly upon the lowest classes of the agricultural population. The most marked decrease occurred in the following towns: Vellore, Trichinopoly, Kurnool, Conjeeveram, Calicut, Masulipatam, Madras.

Deaths in Municipalities.—The total deaths registered was 85,266, representing a death-rate of 35·4 per 1,000. The death-rate was considerably above normal in Bellary

* Unless otherwise stated throughout this Report, figures enclosed in brackets refer to rates per 1,000.

(48·1), chiefly due to cholera and plague; in Chingleput (38·4), where owing to the smallness of the population the deaths from fever have made an increase more apparent than real; in Berhampur (40·5), chiefly under fevers and cholera. In Madras the exceedingly heavy rate of 55·5 per 1,000 occurred. This, however, represented but an increase of 14·6 upon the quinquennial average, and was due to death registration under cholera and fevers.

The total average infantile mortality in municipalities was 237·3 per 1,000 of births. This represents an increase of 14 per 1,000 when compared with last year, and may possibly reflect the influence of the continued strain of prices already discussed, in addition to the usual factors of insanitary environment, and ignorance of hygienic care of infants characteristic of the uneducated Hindu mother. The rate may be contrasted with that obtained under the very unfavourable conditions of town life in England. There the total average of 55 towns yields a rate of 182, and in London 166 per 1,000. In the following towns, the rate of infantile mortality was particularly heavy:—Berhampur (273.6), Bezwada (277·4), Madras (328·4), Vániyambádi (293·6), Palamcottah (240·4), and Tuticorin (304·4). Lest, however, an exaggerated idea of these undesirable rates be entertained, it may be stated that in at least three towns in England they are exceeded. As in the case of rates referred to in the paragraph above on deaths in districts, which include data derived from rural areas, the mortality of male infants in municipal towns was greater than that of females—the rate being 227·6 for the latter, against 246·6 per 1,000 for the former. That male infants should more readily succumb to unfavourable circumstances in the first year of life, accords with experience in all countries. Normally, births of boys are greater than of girls—for example, for the whole Presidency during the year under review, 100 girls were born for every 104·2 boys; but, by the end of the first year of life, the proportion becomes more equal, as the boys die at a greater rate in the earlier months than the girls. The native tendency is to regard the addition of a male infant to the family as of considerably more moment than of a female. Nevertheless, in this Presidency, this feeling is by no means so marked as to lead to neglect of female infants. The utmost that may occur in this direction is that, in times of marked scarcity, the female may occupy an inferior place in the table of precedence as to choice of supplies.

In former years the mortality of infants from small-pox was regarded by the native population as inevitable. Under the influence of compulsory vaccination, however, the saving of infantile life is becoming yearly more evident. Up to 1894, in certain municipalities compulsory vaccination was optional, subsequent to that date it has been adopted in all municipalities. Since 1900 it has been advanced, on the *festina lente* principle, in rural areas. With the bulk of the rural population vaccination, however, is still optional. If the conditions of 1891 and 1901 be contrasted, it is found that, in 1891, the death-rate from small-pox of infants under one year of age in municipalities was 8 per 1,000 of births, against 7·3 per 1,000 of births in rural areas; whereas, in 1901, the deaths in municipal areas of infants under one year of age from this disease amounted to 2·7 per 1,000, against 8·6 per 1,000 in rural areas. It is thus evident whilst in rural areas, in the years contrasted, the rate of mortality of infants from this cause had not decreased, in municipal areas there was a marked improvement as a result of better vaccination. It need not be said that were the infants liable to vaccination earlier than at six months of age, much more favourable results might be expected. In the hope of securing that guardians of infants born in a rural area under compulsory vaccination shall not evade the provisions of the law by proceeding to a municipality, or *vice versâ*, I have advised Government to secure special legislation. By this means a better grade of protection of infant life can be secured.

Chief Diseases.

Cholera.—There were 81,370 deaths from this disease during the year, or a total of 2·2 of the whole population. Anantapur (4·5), Cuddapah (4·2), North Arcot (4·1) and Salem (5·1) were the districts which chiefly suffered. The municipal towns of Chingleput, Coimbatore, Erode, Karúr, Berhampur, Nandyal, Palni, Calicut, Cochin, Gudiyáttam, Salem, Vániyambádi, Tirupattúr and Mangalore gave rates above 5 per 1,000 from this disease. As to prevention, it cannot be said that either Local Fund, Municipal or Revenue authorities are yet alive to the necessity of taking action during the advance of cholera. In spite of appeals from this office, they take advantage of the discretion allowed them in the rulings on the subject issued by Government, and do not think of appointing staffs until cholera is in their midst, and even then (in the interests of so-called economy) they

allow these to be incomplete. So long as this condition continues no real stand against cholera can be made.

Of the total of 6,822 deaths from this cause in 61 municipal towns, no less than 1,161 occurred in Madras town, or 2·4 per 1,000 of its population. Notwithstanding the expenditure of several lakhs of rupees upon its public water-supply, the Madras Municipal Commission is content to allow the inhabitants to supplement it by the use of innumerable wells that are open to pollution, and are sunk in a foul subsoil. Under the circumstances, the town must be regarded as having escaped well out of evil conditions. The day that its long open water channel becomes contaminated with cholera or typhoid matter will, however, be one not so readily reckoned with. The towns of Coimbatore, Erode, Chingleput, Karúr, Berhampur, Cochin, Gudiyáttam, Vániyambádi, Palamcottah and Tuticorin—all of which have water-supplies readily open to fæcal pollution—chiefly suffered in mufassal areas.

Small-pox.—The total deaths from small-pox amounted to 26,202, against 27,692 of the previous year. The rate of incidence in municipal towns where compulsory vaccination is in force was ·6 per 1,000, against ·7 per 1,000 in rural tracts, in a few unions only of which compulsion is exercised. If the town of Cochin be eliminated, where no fewer than 313 deaths occurred from this disease, the incidence on the total municipal population was 0·5 per 1,000. The large mortality in Cochin was doubtless due to the fact that it adjoins an area under independent native administration, where more care is requisite as to small-pox. Of 2,750 children personally inspected by District Medical and Sanitary Officers during their periodical sanitary inspection of schools, 449 or 16·3 per cent. were found unprotected by vaccination. But of these no less than 70·2 per cent. had undergone small-pox. Of the 2,301 children below and above 10 years of age, who had been vaccinated, the rate of attack by small-pox was ·5 per cent.

Plague.—During the year, there was, in the whole Presidency, a total of 3,960 attacks of plague, with a mortality of 76·6 per cent. There were 1,496 cases in municipalities, of which 702 and 769 occurred in Bellary and Vániyambádi respectively. The town of Bellary was infected by cases imported from the Bombay Presidency, and concealed by house-holders. In all other parts, infection was derived directly or indirectly from the Mysore Territory, which continued to be a source of peril to this Presidency. Disregarding importation from that area by other routes, no less than 120 cases of plague were removed from the trains at the Inspection Station of Jalarpet.

The passport system was extended for purposes of surveillance to contacts. Brushes were used universally for the distribution of disinfecting solutions (which method seems to me erroneous except where smooth or greasy walls are concerned), whilst the sheet anchor of compulsory evacuation (when indigenous plague becomes uncontrollable) was not employed. The passport system gave satisfactory results, and granting there is no reason to doubt that the chances are always that a single neglected imported case may cause an epidemic, numerous localities have been saved from the incidence of plague by prompt discovery of such cases.

Fevers.—294,854 persons died from diseases which are registered under this head; these doubtless are chiefly malarial. Every effort has been made to induce local bodies to turn to advantage the modern dictum as to the rôle of the mosquito in the prevalence of malarial fevers. Some of them have treated the matter with extreme apathy, others have promised to make the desired efforts, whilst others have assigned as their reason their inability to discover that any action is requisite as no malarious spot exists within their control, notwithstanding the fevers shown in their mortality statistics. The District Board of Kurnool has placed at my disposal the sum of £33 towards an experiment to exterminate malaria in a village. This sum is probably below requirements, but it at least exhibits on the part of the district board a wish to make advance in the interests of the inhabitants of a notoriously malarious district. In the matter of distinguishing the various diseases now registered under fevers, little advance can be made until a correct system of registration can be afforded by the country. A diagnosis of typhoid fever is common enough on the Nilgiris and at times in Malabar and South Canara, but is rare in the plains, although I have personally seen cases, from time to time, amongst pure natives in the Trichinopoly and Kernool districts. Mr. Lafrenais, Acting District Medical and Sanitary Officer, Nellore, however, has recently reported to me several cases of typhoid fever in Nellore. The chief supply of this town is a tank that (although I understand improvement has lately been evident) I have on more than one occasion represented to the municipal council was contaminated with fæcal matter to an extraordinary extent.

I will shortly investigate some of these cases by Widal's test. Lieut-Colonel Wilkins, District Medical and Sanitary Officer, Malabar, has sent me a list of 73 cases treated in the various hospitals in his charge during the last ten years. He has also supplied an interesting note, which affords conclusive clinical evidence of the nature of the disease. After quoting similar evidence in his experience in Madras City, he states: "I have kept a careful watch to see whether it was really typhoid or true remittent fever prevailing in this district. For the past six years, I have seen several cases both in hospital and private practice, and I am convinced that the disease prevalent in this district among natives is typhoid. The disease is mostly prevalent about the end of July, the whole of August and September, and then gradually becomes less towards October and November. In other words, it begins with the rise of the subsoil water, is most prevalent at the time the water is almost on a level or within a few feet of the surrounding soil and gradually becomes less as the water subsides. In many cases, if the younger members have escaped one year, the next or perhaps the second year another resident in the house is attacked and this one can easily understand when one knows that all the excreta from a typhoid patient are simply thrown away in most cases near the well, where the bed pan is washed or a plantain leaf, which is used in its stead, is disposed of. It is quite possible that the germs of the disease soak into the soil and as the subsoil water rises, are carried into the wells from which the drinking water is obtained and then the infection passes to those who at the time are predisposed to the disease."

Dysentery and diarrhœa.—In contrasting municipal towns with rural areas, the difference in extent of mortality from dysentery and diarrhœa is marked. For the whole Presidency the rate is 1·1 per 1,000, whereas for the municipal towns it amounts to 5·0. Such a result but illustrates the effect of the aggregation of human beings upon filthy and sewage sodden soils, *plus* water supplies open to contamination. In the following towns the rate was particularly heavy:—Chingleput (9·4), Madras (9·7), Periyakulam (8·0), Gudiyáttam (9·2), Palamcottah (15·5) and Tuticorin (10·1).

Injuries.—The total number of deaths due to injuries was 12,872, or at the rate of 0·3 per 1,000. There were 1,672 suicides, which yield a rate of 0·04 on the whole population. As usual in native life in this Presidency, the proportion of females who committed suicide was much greater than amongst males, namely, for every 100 females 80·0 males; whereas, in Great Britain, it is about 100 females to every 312·8 males. The total deaths from snake-bite and wild beasts amounted to 2,022.

All other causes.—Having regard to the existing system of registration, necessarily, a large number of cases cannot be classified. The result is that no less than 42·2 per cent. of the total mortality is placed under this head.

Sanitary Works.

Municipalities.—In my report for 1899, I called attention to the fact that, whilst on the basis of the statistics available, it would be out of the question to be dogmatic on the subject, there was reason to hold that with the introduction of public water supplies into towns—replacing, in great part, old supplies of shallow wells and tanks—there was evident a fall in the fever rate. I ascertained that, about the same period, Major Rogers, Professor of Pathology, Calcutta, had also pointed out, as a result of careful investigation throughout an extensive malarious area, that he had found where the inhabitants were supplied with filtered water the incidence was less than where unfiltered water was employed. To dare assert that the current literature rôle of the mosquito does not cover the *whole* question of epidemiology of malaria in the present day, is to proclaim oneself decidedly heterodox. To prevent this charge being hurled at me, I may, therefore, state I accept fully the truth that has been proved "up to the hilt" that malaria is conveyable by the mosquito. As I understand it, Major Rogers also entertains no heterodox views. There are, however, blanks in the history of the epidemiology of malaria that demand attention, and this cannot be secured if all matters—involving the mosquito or not—be not placed on record. Statistics in this Presidency show that the more perfectly water-supply has been extended to a town the less is the fever rate notwithstanding that, in the absence of drainage systems, it is exceedingly likely that "anopheles pools" have been much increased. Where the inhabitants by choice use largely the old water-supplies —such as in Madras City—and where the amount is so insufficient as to cause the people to still use them *nolens volens* unsatisfactory results occur as seen in Madura and

Dindigul where no improvement of rate has been obtained. It may, at once, be objected that the improvement in the fever rate is probably not in regard to malarial fever but in respect to typhoid—a water-borne disease. This may be so ; I am not in a position to say much against such a theory, beyond that whilst typhoid probably exists in South India much more than has hitherto been stated, its prevalence is not likely to be so great as to account for the difference. I am content to place the facts on record ; they will form a basis for further enquiry. To secure some (admittedly rough) method of ascertaining the value of these figures, I have excluded, for reasons stated, the three towns above mentioned and have compiled total averages for the six towns concerned, and for seventeen other towns of about the same average population that have *not* had water-supplies introduced up to date—so as to ascertain whether errors in registration, or a "wave" of malaria prevalence, in certain years, have had anything to do with the matter.

It is found that in the six towns (aggregate population 280,979) the average fever death-rate for five years prior to introduction of water-supplies was 8·9 per 1,000, but that, subsequent to introduction, it was reduced to 5·4 per 1,000 ; whilst the total death-rates in the same period were 30·4 and 26·1 per 1,000, respectively—implying in a decade a saving of over 12,000 lives. In the group still unprovided with water-supplies (aggregate population, 754,034), the quinquennial period ending 1896 gave a fever death-rate of 6·3 and the following quinquennium 6·0 per 1,000 ; whilst the total death-rates for the respective periods were 26·8 and 28·2 per 1,000. The increased total death-rates shown in the second group of towns is probably really due to improved registration and not to actual greater mortality—a factor which being common to both groups is of importance. It is noteworthy that in Coonoor where a sewerage system has been completed, the fever rate has declined ; whereas no influence is noticeable in Kumbakónam which possesses a system for relief of surface and, partly, of subsoil water.

It is, unfortunately, not probable that much advance in large sanitary works, such as those for water-supply and sewerage, will be recorded in future Sanitary Reports of this Presidency, having regard to a recent ruling by the Government of India that grants-in-aid will not be given to local bodies. It goes without saying that the financial position of the majority of municipalities is such as to preclude the possibility of their successfully attempting to meet the full charges, without aid from Government. Indeed, although much experience has not been gathered on the point, it would seem that even were municipalities willing to attempt to secure loans in the market for the full cost of works, there chances of success would be extremely doubtful. As an instance, I may point to the case of Tanjore, where a sanitarily good and financially profitable scheme for utilizing sewage has been in abeyance for several years, because it cannot secure a loan of £2,200 in the open market.

During the year, no sanitary works of any importance were completed, except the extension of the water-supply of Trichinopoly to one of its suburbs—Worriur. The progress in sewage farming, sewage filtration, and the employment of town rubbish and night-soil, and sewage filtrates for cultivation purposes continues. The Government of Madras has sanctioned a series of experiments on the latter subject.

District Boards.—District Medical and Sanitary Officers inspected 424 towns and villages, and forwarded copies of their reports to this office and to local bodies concerned. Extracts from these were sent to Presidents of District Boards and Municipal Chairmen, and special enquiries were made as to action taken in numerous instances. Where expenditure involved is of a trivial nature, action has usually been taken and, on the whole, much useful improvement has thereby resulted in regard to rural water supplies, conservancy, and the sanitation of schools. As, however, explained in former reports, so long as the small funds available are frittered away by petty allotments under Taluk Boards and Unions, no solid improvements under District Boards can be expected. Having regard to the fact that 50 per cent. of the total funds available under District Boards must be spent on roads, very little money falls to the share of sanitation—efforts as to which can always be conveniently postponed to that happy period "when funds are available." It is time that a definite percentage of available funds be given for current sanitary expenditure.

The maintenance of Village Sanitary Inspection Books has been satisfactory during the year.

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER FOR BOMBAY FOR 1901.

(*Lieutenant-Colonel J. W. Clarkson, I.M.S.*)

General Population.

European and Eurasian Vital Statistics.

The European Census population of 1901 in the Bombay Presidency, exclusive of Cantonments in quasi-foreign territory, is 18,804. During the year 1901, 217 births and 251 deaths were recorded against 260 and 373 in 1900. A birth-rate of 11·54 per 1,000 against 14·06 in 1900 and a death-rate of 13·35 against 20·17. By sexes 120 males and 97 females were born against 150 and 110 in 1900, and as regards deaths 162 males and 89 females died against 222 and 151 in 1900. The very low birth-rate among Europeans is due to the excessive proportion of the male element in that population.

The Eurasian Census population of 1901 is 6,557. During the year 1901 the births registered were 133 against 149 in 1900 and deaths 180 against 247, the rates being 22·84 per 1,000 against 17·49 in 1900 and 27·45 against 28·99. Of those born, 66 were males and 67 females against 79 and 70 in 1900; as regards deaths, 95 males and 85 females died against 125 and 122 in 1900.

Native Population—Vital Statistics.

Births.—In the Presidency of Bombay, including Sind, during the year 1901, there were 465,647 births registered against 505,662 in 1900. The recorded births for the year under report were less by 40,015 than the number registered in the previous year, and also less by 177,067 than the decennial mean ending 1900. In only eight districts, Khándesh, Ahmednagar, Sholápur, Ratnágiri, Bijápur, Sukkur, Lárkhána, Upper Sind Frontier, did the number of births exceed the deaths. The recorded birth-rate for the year was 25·19 per 1,000 the lowest for the past ten years, against 26·87 in 1900 and a decennial mean of 34·15, a result probably due to weakness induced by famine. The number of births recorded during the year is less in every collectorate than in the previous year except Khándesh, City of Bombay, Ahmednagar, Broach, Kaira and the Upper Sind Frontier.

The Deputy Sanitary Commissioner, Sind Registration District, attributes the low birth-rate recorded in Thar and Párkar district as probably due to the exodus caused by scarcity.

There were 242,382 male and 223,265 female births recorded during the year against 262,837 and 242,825 in 1900. For every 100 female births 108·56 male births were recorded during the year.

The following statement shows the number of births recorded in each year since 1891 :—

Year.	Number of Births.	Year.	Number of Births.	Year.	Number of Births.
1891	682,677	1895	674,304	1899	685,348
1892	650,667	1896	691,847	1900	505,662
1893	664,305	1897	629,693	1901	465,647
1894	660,268	1898	582,371		

It is of interest to note that the effect of famine on the birth-rate began to show itself in April 1900, reached its climax in March 1901, and passed off in December 1901, when the birth-rate again reached the mean of the previous ten years.

The recorded birth-rates among the urban and rural populations of the Presidency were 22·72 and 25·57 against 23·72 and 27·30 in 1900. Except in the collectorates of Thána, Ratnágiri, Surat, Kaira, Panch Maháls, and throughout Sind the birth-rates were higher among the rural than the urban population. The difference is very marked in the Poona Collectorate where the rural birth-rate is 29·63 against 11·70 among the urban. Plague had doubtless a certain effect in producing this result, as many families were sent away and the very severe outbreak of 1900, when 4,325 deaths occurred, would show its effect on the birth-rate of 1901 ; but the chief cause is defective registration, no prosecution being instituted under the existing bye-laws. Defaulters may be discovered, but at present it appears to be no one's duty to prosecute.

Out of 56 towns and seven cantonments in the Presidency, one had a birth-rate exceeding 40 per 1,000. Poona, Gogho, Karád, Panvel, Sátára, Bombay, Bulsár, Belgaum, Alibág, Ahmedabad and Kalyán Towns, and Ahmedabad, Deoláli and Ahmednagar Cantonments have very low birth-rates.

Deaths.—Among the Native population in the rural town and cantonment circles in the Presidency, 686,134 deaths were registered during the year 1901. In 1900, 1,318,783 deaths, or 632,649 more than in 1901, were recorded.

The following statement shows the number of deaths recorded in each year since 1891 :—

Year.	Number of Deaths.	Year.	Number of Deaths.	Year.	Number of Deaths.
1891	513,132	1895	538,540	1899	672,269
1892	611,742	1896	596,472	1900	1,318,782
1893	511,831	1897	749,916	1901	686,134
1894	607,179	1898	548,825		

Of the total deaths registered, 357,586 occurred among the males and 328,548 among females against 706,275 and 612,508, respectively, in 1900. The death-rate per 1,000 in 1901 was 37·12 against 70·07 in 1900 and a decennial mean of 35·43.

The millesimal rate of males dying to males living was 37·52 and of females dying to females living was 36·70. In 1900 these ratios were, respectively, 72·53 and 67·43. For every 100 females who died, 108·84 deaths among males were recorded, but these proportions vary considerably, as in Bombay City the ratio of males to females deaths was 147·87, in Karáchi 134·95 and Násik 110·71.

In the Western, Central, Southern, Gujarát and Sind Registration Districts the number of deaths recorded in 1901 were 164,469, 147,526, 187,058, 120,998 and 66,083 and their ratios per 1,000 37·18, 30·53, 56·77, 44·79 and 20·61, respectively. The highest death-rate occurred in the Southern Registration District, which suffered from plague and cholera, and also famine. In the other districts the death-rate was below the decennial mean.

In the year 1901 the recorded death-rates per 1,000 of population which ranged from 77·78 in the City of Bombay to 13·21 in the Upper Sind Frontier were lower than in 1900 in all the collectorates except Sátára, Belgaum, Dhárwár and Kánara.

The Deputy Sanitary Commissioner, Southern Registration District, remarks that the high death-rates in the Belgaum and Dhárwár Collectorates were chiefly due to plague.

Comparing the birth and death-rates in each collectorate for 1901, the birth-rate in the City of Bombay was much below the registered death-rate 17·48 and 77·78, respectively : this may be ascribed to plague on the one hand and defective registration on the other. In the following collectorates the recorded birth-rates are lower than the registered death-rates :—Thána, Poona, Sátára, Belgaum, Dhárwár, Broach, Ahmedabad and Thar and Párkar.

Deaths by ages.—As regards deaths by ages, the figures show that the ratio per 1,000 of population the largest number of deaths took place in the period "under five years" and the next in the age period "20 years and under 40" the lowest ratio being in the period "15 years and under 20" of the percentage.

The number of male births during the year was 212,082 while the male deaths under one year were 48,022 or 198·12 per 1,000. Among females the numbers were 223,265 and 42,260, respectively, the ratio being 189·28 per 1,000. In England in 1899 the proportion of deaths of infants under one year of age to registered births was 163 per 1,000, the death-rate for the whole population being in that year 18·3 per 1,000.

As the general death-rate in the Bombay Presidency was 37·12 per 1000 in 1901, it will be seen that infantile mortality is not relatively high in this country. Bombay City, however, compares very unfavourably with the rest of the Presidency, as it gives a male infantile mortality of 571·39 on the births, the female ratio being 589·80. ' A point to be noted being that the female ratio is higher than the male.

Deaths by causes.—The subjoined table shows the deaths in 1901 arranged according to the specified causes laid down by the Government of India, and contrasted with the results for 1900 and with the mean of the preceding five years. The "causes of deaths" will be briefly noticed in the next section :—

Causes of deaths.	Mean for 5 years, 1896–1900.		1900.		1901.	
	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.
Cholera	53,870	2·86	163,889	8·71	13,600	·74
Small-pox	4,788	·25	9,885	·52	5,340	·29
Plague	53,003	2.82	33,196	1·76	128,259	6·94
Fevers	360,775	19·17	543,319	28·87	291,951	15·80
Dysentery and diarrhœa ...	94,356	5.01	218,243	11·59	60,198	3·26
Injuries	7,091	·38	8,224	·44	7,092	·38
Other causes	203,370	10·81	342,027	18·17	179,694	9·72
All causes	777,253	41·30	1,318,783	70·07	686,134	37·12

The greatest number of deaths (73,187) took place in October and the least (37,335) in June. In 1900 the greatest and least numbers occurred in July (162,555) and December (66,250).

The recorded death-rates among the urban and rural population of the Presidency were respectively 57·85 and 34·01 per 1,000 of population against 102·33 and 65·57 in 1900. Among the rural population the death-rate was higher than in the urban population in the collectorates of Belgaum, Kánara, Surat and Ratnágiri.

Chief Diseases.

Cholera.—In the year 1901, there were 13,600 deaths recorded as due to cholera contrasted with 163,889 deaths from the same cause in 1900. The disease was somewhat severe in the districts of Dhárwár, Belgaum, and Bijápur, where 7,648 or 6·87, 2,851 or 2·87, and 1,431 or 1·95 deaths per 1,000 of population took place, respectively. In Kánara 657 deaths occurred and in Sholápur 524. In Bombay City a few deaths took place every month, giving a total of 197 for the year. The collectorates of Khándesh and Thána gave eight deaths each, Násik 12, Ahmednagar 75, Poona 38, Sátára 50, Kolába 100, and Ratnágiri three. Sind was entirely free and practically also Gujárat, only one death being reported from Ahmedabad.

In December, 1900, cholera deaths were reported from the districts of Poona, Ratnágiri, Belgaum, Dhárwar, Bijápur, Kánara, Karáchi, Hyderabad, and Bombay City. In January of the year under report, the disease continued in five of these districts—Belgaum, Dhárwár, Bijápur, Kánara, and Bombay City, and there were 1,086 deaths reported. In the month of February the same collectorates, except Bijápur, returned deaths, Ratnágiri being affected in addition. In March the mortality rose to 2,763 deaths, and reached its maximum in April in which month 3,016 deaths were recorded. From May the mortality declined month by month till July when the collectorates of Násik, Thána, Kolába, Poona, and Sholápur were affected in addition. There was a slight increase in the number of deaths in August. From September the mortality rapidly fell, but the disease continued to the end of the year, causing nine deaths in the City of Bombay in the month of December, all other collectorates being free.

By seasons.—The greatest number of cholera deaths, 5319, occurred in the cold season of 121 days, against 6,870 during the same period in 1900; whilst in 1900 the greatest number, 106,193, took place in the rainy season of 122 days, during the year under report the number was only 3,371; 4,682 deaths were recorded in the hot and dry season of 61 days, against 4,805 in the same season last year. In the hot and damp season of 61 days (October and November), 228 deaths were recorded, against 2,811 during the same season of 1900.

Fifteen collectorates were affected by cholera, in 11 of these the death-rate per 1,000 was below one. In the remaining four, Dhárwár recorded a death-rate of 6·87 the highest more than three times the quinquennial mean 1·90, followed by Belgaum with 2·87; in Bijápur and Kánara it was 1·95 and 1·44, respectively.

Out of 220 rural circles or tálukas, 65 were affected by cholera during the year, against 201 in the previous year. The disease principally prevailed in 13 of these and gave a ratio of above 4 per 1,000 of population. The tálukas of Hángal and Bankápur in the district of Dhárwár suffered somewhat severely and gave out 1,208 and 1,396 deaths, or a ratio of 15·53 and 15·45 per 1,000 of population, respectively.

Out of 56 town circles in the Presidency, 18 were affected by cholera, and in most of these the epidemic was chiefly confined to the head-quarter stations of the affected districts. The largest number of deaths, 197, was recorded in the City of Bombay, but the highest ratio, 15·76 per 1,000 of population, took place in Kaládagi in the district of Bijápur.

The affected area included 916 out of 25,846 villages in the Presidency, against 8,461 in 1900. The highest percentage took place in the collectorate of Dhárwár, 467 or 35·98 per cent. of villages were affected. In Belgaum, Bijápur, Sholápur, and Kánara, the percentages were 18·17, 10·12, 4·89, and 4·35, respectively, and in the remaining collectorates the percentages were below one per cent.

Small-pox.—There were 5,340 deaths from small-pox (2,808 males and 2,532 females), against 9,885 in 1900, and a decennial mean of 3,724. The mortality, although less than that of 1900, was higher than that of the year 1897-98 and 1899, and also of the mean for 10 years ending 1900. Only two collectorates, Kánara and Ahmedabad, were free from the disease. The Southern Registration District records the highest mortality—2,686, next in order comes Central with 947, Western with 797, Sind with 786, and Gujarát with 124. In the year under report, 21·82 per cent. of deaths occurred amongst infants under one year of age, whilst 46·68 per cent. took place among children one to 10 years, the remaining 31·50 being among persons over 10 years of age.

Fever.—There were 291,951 deaths registered under the heading fever (152,285 males and 139,666 females), against 543,319 in 1900; thus there was a decrease of 251,368 deaths as compared with the previous year; the decennial mean is 405,494 which includes the deaths from plague for the past five years. The death-rate was 15·80 per 1000 as compared with 28·87 for the previous year and a decennial mean of 12·55, and this includes the deaths from plague during the years from 1896 to 1900. Like the year previous, the Gujarát Registration District recorded a high death-rate, but much lower than that of 1900, which gave an exceptionally high rate. The mortality for the district was 78,628, next comes Western with 62,403, Central with 60,556, Sind with 54,553, and Southern with 35,811.

In the collectorates of Ahmedabad, Broach, Kaira, Panch Maháls, and Thar and Párkar high ratios are observed; this result is due apparently to famine causes to a great extent.

The number of deaths in each month during the year was lower than in the corresponding month of the previous year. The lowest mortality—15,676—was reported in July and it gradually rose till November, when 28,835 deaths were recorded, and 28,438 in December.

Plague.—During the year under report 128,259 deaths were recorded from plague—an increase of 95,063 deaths as compared with the previous year.

The number of deaths ascribed to plague in each year since 1896 is as follows :—

Year.	Number of deaths from Plague.	Year.	Number of deaths from Plague.	Year.	Number of deaths from Plague.
1896	2,086	1898	86,191	1900	33,196
1897	46,944	1899	96,596	1901	128,259

The mortality from this disease during the year was the highest recorded since its first appearance in 1896. All the collectorates in the Presidency, except Thar and Párkar, Lárkhána, and Upper Sind Frontier were affected.

The collectorates most affected were those of Belgaum, Dhárwár, Sátára, and the City of Bombay, with a death-rate of 34·07, 28·65, 19·26, and 24·58 per 1,000 of population, respectively. Karáchi came next with a rate of 7·0, and then followed Broach, Surat, Poona, and Thána with rates which ranged between four and five. The collectorate of Khándesh, in which eight deaths were reported during the previous year, returned 2,676 deaths, followed by Kolába with 1,116 against 140 deaths during 1900. The district of Kánara recorded 527 or 1·16 deaths, while in the remaining affected collectorates the rates were low. The rates per 1,000 for the various Registration Districts were as follows :—Western 6·01, Central 5·54, Southern 20·11, Gujarát 20·1, and Sind ·98.

In January there were 2,587 deaths reported, and during March they rose to 8,000. In April the deaths fell and continued to fall until the minimum (2,291) was reached in June ; they rose again in July, and a more distinct rise continued until October when the maximum, 25,193, was recorded, after which they continued falling until December in which 18,109 deaths were recorded.

There were 1,582 towns and villages affected by the epidemic, against 587 during the previous year.

Dysentery and Diarrhœa.—Dysentery and diarrhœa caused the deaths of 32,907 males and 27,291 females, or a total of 60,198 persons, against 218,243 in 1900, and a decennial mean of 64,788, a decrease of 158,045 against last year, and 4,590 less than the decennial mean.

The deaths ascribed to dysentery and diarrhœa during the seven years preceding 1897 showed only slight variations, but have since 1897 shewn a great increase. In the famine year of 1897 there was a sudden increase, which is but natural in a year of scarcity, and was repeated to an even greater extent in the year 1900. But in the year under report these deaths fell below the decennial mean.

The Central Registration District records the ratio of 5·35 per 1,000 of population, against 14·25 in 1900, and 4·73 the decennial mean. The Western Registration District comes next with a ratio of 4·50, the Southern Registration District 3·65, the Gujarát Registration District 1·32, and the Sind Registration District 0·21. In the Presidency the rate was 3·26, against 11·59 in the previous year, and a decennial mean of 3·44. All the collectorates excepting Dhárwár and Kánara show lower ratios than the previous year ; the highest ratio—8·12—was recorded in the collectorate of Sholápur, followed by Ahmednagar and Belgaum with 6·68 and 6·24. In the collectorates of Poona, Khándesh, Sátára, Bombay, and Násik, the recorded death-rates were 5·72, 5·60, 4·93, 4·85, and 4·43 respectively, while in Ratnágiri, Kolába, Dhárwár, and Kaira they were between two and three per 1,000 of population.

In each month of the year the deaths ascribed to these causes were lower than those of the previous year, and were also lower than the decennial mean in the months from April to October.

Injuries.—During 1901, 4,007 males and 3,085 females, or a total of 7,092 persons, met with violent deaths. The mortality from these causes is less by 1,132 than that reported in 1900, and corresponds within a unit with the five years' mean. Of the 7,092 deaths, 3,138 occurred from drowning, 1,199 from snake-bites, 841 from wounding, 187 from hanging, 121 from poisoning, 168 from attacks by wild beasts, and 1,438 from other causes.

Other Causes.—The recorded deaths from causes other than those specified, number 179,694, of which 91,961 occurred among males and 87,733 among females, lower than that for 1900 by 162,333. In all the registration districts there is a large decrease in the number of deaths as compared with the previous year. The highest number of deaths, 27,777, was recorded in the City of Bombay, followed by Dhárwár and Kaira with 22,490 and 14,333 respectively, and the lowest (117) in each of the districts of Thar and Párkar and the Upper Sind Frontier.

Sanitary Works.

During the year ending 31st March, 1901, there were 165 municipalities in the mofussil with a population, according to the Census of 1901, of 2,349,729 souls; the total income of these municipalities, including balance in hand on 1st April, 1900, amounted to £479,894. Out of this sum £95,168 was expended on improving the water-supply, drainage, and conservancy within municipal limits.

There are 23 District Local Boards, with 207 Táluka Local Boards; the entire income of these Boards during the year ending 31st March, 1901, amounted to £272,325, and out of this sum £11,566 was expended on water-supply and drainage.

The Bombay Village Sanitation Act of 1889 has been introduced into 292 villages, there being no increase in the number this year. It would appear that owing to famine and plague, which claims the attention of the District officers, no progress has been made.

The number of selected villages in which the Village Sanitary Inspection Book has been introduced, stands at 3,395; of this in about 1,545 villages the book has been written up by the officers of the Sanitary Department.

General Remarks.

The year opened with famine conditions prevailing in the collectorates of Ahmedabad, Panch Maháls, Broach, Khándesh, Ahmednagar, Sholápur, Poona, Násik, Sátára, and Bijápur. There were 28 famine relief camp and 18 poor-house hospitals open during the month of January, 1901, and the number gradually increased till July, when there were 55 famine relief camp and 15 poorhouse hospitals open at one time. The rains having practically failed in the Gujarát districts, and being below the average in some of the Deccan districts, famine conditions continued until the close of the year in the collectorates of Ahmedabad, Panch Maháls, Ahmednagar, Sholápur, and Bijápur. During the year under report there were 36,444 admissions into the famine relief hospitals and 6,134 deaths. The maximum number of admissions and deaths, 5,135 and 1,091 respectively, took place in the month of August, and the minimum in December, with 438 admissions and 192 deaths.

During the year 1901, 36,444 in and 117,808 out-door patients were treated in the 124 different famine relief camp and poor-house hospitals, and 6,134 deaths. The greatest number of deaths in camps, 2,114, occurred in the Sholápur district, followed by Ahmedabad with 1,189 deaths, Ahmednagar with 1,045, Bijápur with 803, Poona with 515, Panch Maháls 114, Belgaum 109, Sátára 98, Násik 81, Khándesh 62, Kaira 3, and Broach with 1 death.

The highest number of deaths, 2,479, was due to dysentery and diarrhœa, from which 991 deaths took place in the Sholápur district, and 582 deaths in the Ahmedabad district.

Cholera first made its appearance on the "Sholápur-Bellari Road" relief camp in the Bijápur district on 25th May, 1901, and spread gradually to most of the relief camps in that district, and 219 deaths were recorded. It then broke out at the Budhial Camp in

the Sholápur district on 10th August, 1901, and was confined to only four relief camps, with 280 deaths. The only other collectorate where famine relief camps were affected with cholera was Belgaum district, with 10 deaths.

There were 93 cases of small-pox, with only one death, in the Ahmednagar district. There were 7,757 cases of fever, of which 1,142 proved fatal. The highest number of deaths, 398 out of 2,964 attacks, took place in the Sholápur district. In the Ahmedabad district there were 1,257 attacks and 212 deaths.

One hundred and nineteen deaths were due to emaciation. Of this number 31 deaths occurred in the Sholápur district, 27 in the Ahmedabad district, and 24 deaths in the Ahmednagar district.

The highest number of admissions was from "all other causes," viz., 20,440, with 1,884 deaths. The highest number of deaths, 447, took place in the Ahmednagar district, followed by Sholápur with 419, Ahmedabad with 368, Bijápur with 250, and Poona district with 190 deaths.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF THE PORT OF BOMBAY FOR THE YEAR ENDING 31ST DECEMBER, 1901.

Summary.—During the year under report 34,637 vessels of all sorts with 886,310 crew and passengers, were examined, against 65,966 vessels, with 1,173,050 crew and passengers, during the year preceding. The decrease in the number of vessels, crew and passengers inspected is due to the fact that vessels sailing from the Port of Bombay for ports on the coast of the Kolába District as far south as Roha were exempt from medical inspection in accordance with Government Notifications No. 1697-P. of 17th April, 1901, and No. 3963-P. of 30th September, 1901.

The clothing and bedding of 70,914 native crew and third class or deck passengers who proceeded by vessels to ports out of India were disinfected. The baggage of 1,290 returning pilgrims, 2,671 deck passengers from jigger-infected ports, and 3,939 crew and passengers of other infected vessels which arrived in Bombay was disinfected. 83 vessels of all kinds on which cases of infectious disease occurred before departure from, or before or after arrival at, Bombay were disinfected. 868 crew and passengers were vaccinated owing to the prevalence of small-pox among them. At the outward and inward inspections and on board vessels lying in the harbour and docks 73 cases of plague, 5 cases of cholera, 34 cases of small-pox, 159 cases of measles, 67 cases of chicken-pox, 46 cases of jigger, 3 cases of leprosy, 4 cases of enteric fever, and 1 case of scarlatina were detected. Although it is not necessary to reject cases of chicken-pox, as that disease is not declared by the Government of India as an infectious disease dangerous to life, commanders of vessels, as a rule, refuse to take such people on board, as they are afraid to convey them to other ports where chicken-pox may be considered as an infectious disease.

Statement showing the summary of the shipping of the Bombay Port, and the work in connection therewith for the year ending 31st December, 1901 :—

Vessels, including Country Craft.	Total Number of Vessels.	Number of Vessels inspected.	Number of Persons inspected, including crew on vessels.	Number of Native Crew and 3rd Class or deck passengers disinfected during the year.	Number of Vessels disinfected.	Number of Persons vaccinated	Number of Persons segregated or rejected.	Diseases and Number of Cases of each.							
								Plague.	Cholera.	Small-pox.	Measles.	Chicken-pox.	Jigger.	Leprosy.	Enteric Fever.	Scarlatina.

* These figures are supplied by the Customs Department and the Port Officer, Bombay.

Incoming Vessels.—118 such vessels with 9,534 crew and 17,670 passengers were inspected on arrival. Out of this number 46 vessels entered the harbour with cases of infectious diseases on board. Of the 46 infected vessels, 5 were transports which arrived from Durban with 5,962 crew and passengers, including Boer prisoners. Among these prisoners 145 were found to be suffering from measles, 22 from chicken-pox, 1 from scarlatina and 4 from enteric fever. All these patients were taken over by the military authorities for treatment. The disinfection of the clothing and bedding belonging to the patients and to the crews of the vessels concerned was carried out on the new floating disinfection barge. 23 vessels arrived from East African Ports with 4,448 crew and

passengers, of whom 46 were found to be suffering from ulcers due to jigger. The jigger cases were sent to the Goculdas Tejpal Hospital for treatment. The clothing and bedding of 2,671 deck passengers, including those of the jigger patients, were disinfected at the new disinfection shed situated on the Frere Road, near Prince's Dock. The remaining 18 vessels with 3,940 crew and passengers had on board 2 cases of plague, 10 cases of small-pox, 9 cases of measles and 14 cases of chicken-pox. The disinfection of all the vessels infected, with the exception of one, and of the clothing and bedding of their crew and passengers was carried out in the usual manner. The exception was the S.S. "Setos," which collided with an outgoing steamer while entering the harbour on her arrival from East African Ports on the night of the 14th February, 1901, and was sunk. The crew and passengers of this vessel were saved and allowed to land during the night. As they were wet and had no shelter they were allowed to enter the town and were examined on the following morning.

Four vessels with 1,357 Australian horses and 10 mules were visited on their arrival at this port. The animals were examined by the Principal, Bombay Veterinary College, and certified to be free from tick pest or other contagious disease.

Outgoing Vessels.—During the year under report 34,481 outward bound vessels with 359,927 crew and 499,179 passengers were inspected. At the inspection 6,997 persons were rejected and prevented from sailing. Of the number detained in the Port Health Camp, 51 developed plague.

Of the 34,481 outgoing vessels with 359,927 crew and 499,279 passengers examined during the year, 315 vessels with 34,786 crew and 24,450 passengers left for Aden or ports in the Red Sea and Europe ; 610 vessels with 33,477 crew and 20,169 passengers for other ports out of India ; and the remaining 33,556 vessels with 291,664 crew and 454,560 passengers for Indian ports including Burma.

The clothing, bedding and suspected articles of 45,597 Asiatic and African members of the crew (excluding Japanese crew, who are specially exempt from disinfection) and of 20,432 third class or deck passengers and Asiatic and African servants who sailed on vessels bound for ports out of India were disinfected at the disinfection shed situated on the Frere Road, near Prince's Dock. The disinfection of the clothing and bedding of 4,164 crew of native sailing craft and 721 passengers conveyed by such vessels to ports out of India was carried out by means of the municipal stove attached to the Modikhana Hospital. Thus the total number of crew and passengers whose clothing and bedding were disinfected at the above-mentioned disinfection stations comes to 70,914 during the year under report, against 71,555 during the year preceding.

In certain cases the disinfection of the clothing and bedding of the Native crew of vessels bound for ports out of India *viâ* Karáchi was not carried out at Bombay, as disinfection is again done at Karáchi.

The disinfection shed was fitted with a second sterilizer, so as to enable the staff to get through the disinfection of the kit of crew and passengers of several vessels sailing at about the same time, so as not to cause any delay in their departure.

In addition to the medical examination of crew and passengers which was carried out by day on shore prior to the embarkation as required by the Venice Sanitary Convention Regulations, the ship's company was again inspected on board before the issue of a bill of health immediately before departure from this port. This means that the Native crew of almost all vessels proceeding to ports out of India were, as a rule, examined three times—firstly, when they were shipped ; secondly, when their clothing and bedding were being disinfected ; and thirdly, immediately before the vessel sailed. The first inspection referred to has to be carried out so as to meet the letter of the Venice Convention, but from a sanitary point of view it would appear to be unnecessary, and is, therefore, a waste of time and money, as most of the crew sleep on shore for several nights after the first shore inspection has been carried out.

In April, the "Sicilia" and in October the "Valetta" called at Bombay on their voyage to Colombo, merely to land troops, ordinary passengers and certain Government packages, and did not embark any passengers, or discharge, or take in any cargo here. Nothing was known as to the state of health of the crew and passengers already on board from ports outside Bombay, as they were not medically inspected here ; they came under the proviso of Rule 1 of the Medical Inspection Rules issued under Government Notification, General Department (Plague), No. 3892-P., dated the 14th June, 1899. The bills of health last obtained by these vessels before their arrival at the port of Bombay were accordingly endorsed as laid down in the Notification.

During the year under report 2,271 outgoing steamers and square-rigged vessels were examined. All of them were certified in the bills of health granted to them to have sailed from the Port of Bombay in a satisfactory sanitary condition. The commanders, agents, and nacodas of all outward bound vessels, including native sailing craft, with the exception of very few, were careful in paying attention to the sanitary state of their ships, and in almost all cases they have cheerfully carried out the instructions and advice of the Port Health Officer. The forecastles were limewashed, painted, or disinfected before departure. Owing to the large number of coolies who are employed in discharging coals and other cargo using the 'tween decks and holds of ships for the purposes of nature, it was found to be absolutely necessary to have the decks and holds of ships in ballast thoroughly washed down, and in most cases limewashed or disinfected before the vessel was granted a bill of health. 32,210 native sailing craft were inspected during the year. The bilges of the craft were generally clean at the time of inspection. Those that were found to be dirty or to contain foul water had to postpone their departures until thoroughly cleaned.

Infectious Diseases on Vessels in Harbour.—During the year under report 27 steamers and 11 native sailing craft which were lying at different berths in the Victoria and Prince's Docks and at the various bandars in the harbour, had on board 19 cases of plague, of whom 14 died, 5 cases of cholera, all of which proved fatal, 4 cases of small-pox, 3 cases of measles and 12 cases of chicken-pox. In addition to the above-mentioned cases, four persons (presumably dock labourers) were found dead at certain wharfs in the Prince's and Victoria Docks and at the Modi Bandar Inspection Shed. The cause of death in these cases was attributed to plague. All these vessels and those mentioned in paragraph 3 of this report, as well as the places where the coolies were found dead, were thoroughly disinfected according to the regulations issued under the Venice Sanitary Convention and the Indian Ports Act.

TABLE GIVING DETAILS OF INFECTIOUS DISEASES ON VESSELS WHILE LYING IN THE PORT OF BOMBAY DURING THE YEAR 1901 :—

Months.	Number of Persons who were attacked with Plague at Bandars and in the Docks.		Total Number of Cases of Infectious Diseases in the Bombay Harbour.

Port Observation Camp.—The area of land originally occupied by this camp, at a monthly rent of Rs. 175–10–1, between 10th January, 1899, and 31st August, 1900, was 25,000 square feet. On 1st September, 1900, the land was curtailed to 17,296 square

feet, for which a rent of Rs. 121-1-2 per month was paid to the Bombay Port Trustees. The latter area was occupied by the camp until 1st September, 1901, when it was further curtailed to 12,555 square feet, the monthly rent for which is now Rs. 87-14-2. The area of land referred to was curtailed owing to the recent policy of the Government regarding detention of persons in camps under observation.

This camp received persons who were rejected and sent there from the outward and inward inspections. They were kept under observation until their temperature fell to normal or until it was certain that the symptoms from which they suffered were not due to plague. Among the passengers and crew who were sent to the camp from the outward inspections, 51 developed plague and were transferred to the various plague hospitals in the city for treatment. The sheds of the camp in which the plague cases developed were thoroughly disinfected with perchloride of mercury and were kept unoccupied for some days. All the sheds were thoroughly disinfected twice a week with the standard solution of the perchloride of mercury. One hospital assistant and one ayah were employed to look after the inmates of the camp. The sweeping of the camp was done under arrangements made with the Public Health Department of the Bombay Municipality. The limewashing of the sheds, floors, &c., and the general repairs to the camp were carried out by the Executive Engineer, Bombay Presidency. One of the senior medical officers was detailed in turn every month to supervise the general working of the camp.

Disinfection of Ships and Infected Cargo.—The total number of infected vessels of all sorts disinfected under the personal supervision of the Health Officer of the Port, or of his staff and assisted by the harbour police was 83 during the year. The resident transport officer and the senior naval officer arranged for carrying out the Port Health Officer's recommendations for the disinfection of transports on which cases of infectious diseases occurred. In certain cases the disinfection barge was placed at the disposal of the marine authorities for carrying out the disinfection of linen, mattresses and the clothing and bedding of the crew belonging to infected naval and Indian marine ships or transports.

When disinfecting the vessels on which cases of cholera occurred, the drinking water stored on board such vessels was discharged into the sea and the water tanks were disinfected inside with potassium permanganate solution before they were re-filled with a fresh supply of drinking water.

In April, 1901, dead rats were found for days on board of a ship which was lying in the Prince's Dock. The vessel was disinfected in the following manner, as described by the captain :—

> " Sulphur was burned in the holds. The lower and the upper decks were washed and cleaned and then disinfected with a 5 per cent. solution of carbolic acid. There were three manholes for cargo which were swabbed with a solution of soft soap and carbolic acid and then dusted over with disinfectant powder. The walls and the roof of the manholes were sprayed with the same solution. The forecastles were washed with 5 per cent. solution of carbolic acid. The second class cabins as well as the bath-rooms and the water-closets (both deck and saloon) were also washed with the same solution."

General Health of the Shipping.—During the year 841 persons connected with the shipping were admitted into the various hospitals in the city suffering from diseases other than those considered by the Government of India as infectious diseases dangerous to life. The Saint George's Hospital admitted 457 European patients, of whom 9 died, 419 were discharged, and 29 remained after 1st January, 1902, under treatment. The Jamsetjee Jejeebhoy Hospital admitted 103 Native patients, of whom 13 died, and the Goculdas Tejpal Hospital 281 Natives, of whom 21 died. The diseases for which the patients in question were admitted were due to injuries, ague, simple continued, enteric and remittent fever, beriberi, syphilis, rheumatism, debility, diarrhœa, pneumonia, venereal, abscess, ulcers, &c., &c.

Red Sea Pilgrim Traffic.—The pilgrim traffic from Bombay to Jeddah has been stopped owing to the prevalence of plague in the former place since the year 1897 ; and consequently no vessels with Mecca pilgrims left this port for Jeddah during the year. The number of pilgrims who returned from Mecca *viâ* Aden and other routes during the year was 1290.

The Pilgrim Ships "Naseri," "Hooseinee" and "Pemba" had each a case of small-pox on the return voyage from Jeddah. The cases from the first two vessels were

landed at Karáchi and the case from the last vessel was landed at Aden. The necessary disinfection of the vessels and the clothing and bedding of the Hajees was carried out at Karáchi and Aden. On inspection here the crew and passengers of those vessels were found to be free from any infectious diseases.

The baggage of the 1,290 returning pilgrims was disinfected in the Port Health Disinfecting Stove. Pilgrims whose homes were up-country or beyond the frontier were not allowed to enter the town, but were sent direct from the disinfection shed to their homes by rail at the Government expense.

Sanitary state of the Harbour and Foreshore.—The sanitary state of the Bombay Harbour and Foreshore has continued to be the same as last year. The condition of the various bandars and docks has been reported as satisfactory during the year by the Customs Officers stationed at each bandar, with the exception of Clark Bandar, the condition of which is reported to be "not good." No complaints were made to the Port Health Officer by the residents in the vicinity of the Bombay Harbour as was customary some years ago regarding the insanitary and filthy state of certain bandars, and in the absence of such reports it is inferred that the present condition of the foreshore is as a rule, good.

Presence of Cholera and Small-pox and Epidemic of Plague in the City.—At least 18,736 deaths from plague, 198 deaths from cholera and 159 deaths from small-pox occurred in the City of Bombay against 13,286 deaths from plague, 4,273 deaths from cholera, and 3,018 deaths from small-pox during the year preceding. The City was free from epidemics of cholera and small-pox during the year under report, but plague was raging as a virulent epidemic from January to June inclusive in the year 1901.

The rigorous and very searching examination of each individual leaving this Port, the thorough disinfection of clothing, bedding and boxes of the Native crew, deck and third class passengers proceeding by vessels to ports out of India, and the rejection of persons suffering from suspicious symptoms of plague or other infectious disease have become so well known, that few persons actually suffering from fully developed plague symptoms attempt to travel by sea, as they know they are certain of being detected and detained in camp or hospital.

Whenever plague developed among the crew or passengers who were prevented from sailing on a vessel bound for a Foreign port, immediate intimation of it was sent to Government, with a view to communicating the fact by wire to the authorities at the next port at which the vessel was intended to touch. On the occurrence of a plague case among those who were rejected from vessels bound for Indian ports, the information was given by the Port Health Officer by wire to the next port for which the vessel was bound. This was done so as to give every information to other ports in case those rejections who developed plague may have relatives or friends among the people who sailed on the ship.

With one exception, no lines of vessels that left Bombay met with any vexatious delay owing to quarantine regulations at Foreign ports. This speaks volumes for the faith of Foreign Governments in the efficiency of the measures adopted by Government to prevent the spread of plague from Bombay by sea. The exception referred to is that of the British India steamers, which gave up calling at several ports in Portuguese East Africa on account of the enforcement of numerous vexatious regulations at those ports against arrivals from plague-infected countries.

The following outgoing vessels were reported to have had plague on board after leaving Bombay :—

(i) S.S. *Bormida* left for China on 17th January 1901. One of the passengers was found by the ship's doctor to be suffering from plague symptoms on the 20th January 1901. He died on the 21st idem.

(ii) S.S. *Assyria* left on 7th March 1901. On arrival at Karáchi one of her passengers was found to be suffering from plague.

(iii) S.S. *Parramatta* left on 12th October 1901 for the Far East *viâ* Colombo. A fireman serang is reported to have died off Colombo of plague and was buried at sea.

It was stated in the press that the S.S. *Peninsular*, which left Bombay on 2nd November 1901, landed at Marseilles two suspected cases of plague from among the lascars. From the reports obtained from the Superintendent, P. & O. Company, and their Agents at London and Marseilles, and also from enquiries made when the S.S. *Peninsular* returned to Bombay in January last, there is not the least ground to suppose that the men had plague. Both of them recovered.

The S.S. *Patiala* left Bombay on 26th November 1901 for Aden and East African Ports *viâ* Karáchi. One fatal case occurred among ordnance lascars and was removed at Aden on 5th December 1901. He found to be in perfect health at the time of his departure from Bombay. As the passengers from Bombay were allowed on shore at Karáchi—a plague-infected port—the deceased may have contracted plague there. The man is reported to have developed plague 5 days after leaving Karáchi or 8 days after leaving Bombay. The *Peninsular* and *Patiala* should not be counted against Bombay.

In addition to the above-mentioned cases, some cases of plague may have been exported from Bombay by coasting vessels to the small ports north and south of Bombay, but on the whole they must have been very few in comparison with the large passenger traffic which exists between Bombay and those ports.

Two vessels on their inward voyage were reported to have had cases of plague.

The decrease in the number of plague cases detected is due to the fact that a large number of the rejected were turned into the town and were therefore lost sight of, whereas in previous years they were detained in the various camps erected for that purpose until they showed clear signs of plague or until it was certain that the symptoms from which they were suffering were not due to plague.

In one instance a box said to contain plague-cultures was found by one of the Port Health Staff in the possession of a Surgeon on a ship which sailed from the docks for China. As the conditions laid down in the Rules issued under Government Notifications No. 2999-P. of 3rd May 1899 and No. 6048-P. of 4th October 1899 were not fulfilled the box was returned to the person from whom the Ship's Surgeon received it.

The question of clearing ships of rats at plague-infected ports, or on arrival from such ports at non-infected ports, has been under most careful consideration. Rats may indeed be killed by means of carbonic acid and other gases, but the cost of the operation and the difficulty of removing the gas from the hold of a vessel so as to enable human beings to work the cargo without danger to life and health appear to be at present impracticable. In addition to these and many other difficulties, there is nothing to show that gas liberated in the hold of a vessel will render innocuous plague microbes in the cargo of a vessel or in the body of infected rats on board of ship. I do not see how vessels can be completely freed from rats unless the vessel is empty of all cargo and ballast, and as this cannot be done in wet dock or stream without endangering the stability of the vessel, unless she is in water ballast, nothing short of sending her into dry dock, discharging her cargo there, and then filling the holds, forecastles, cabins and saloons with some poisonous or asphyxiating gas would be effective.

ABSTRACT OF THE REPORT OF THE CALCUTTA MUNICIPALITY FOR 1901-1902.

(*R. T. Greer, Esq., Chairman.*)

Water-supply—Filtered supply.—The Corporation have dealt with the question of providing a continuous water-supply and, having adopted the scheme which Government suggested, they anticipate the completion of the measure within the period prescribed by law.

In view of the statutory obligation of the Corporation, regarding the conversion of the present intermittent system of filtered water into a continuous supply, the Chief Engineer, in April, 1901, submitted a scheme recommending, among other things, the construction of elevated reservoirs, which, he contended, would do away with the necessity of maintaining the existing Pumping Stations at Wellington Square and Halliday Street. He also recommended that the opinion of an expert should be taken on the subject. The General Committee determined to consult the Government, with the result that Messrs. Buckley and Silk were deputed (under Section 22 of Act III., Bengal, 1899) to examine the existing water-supply of Calcutta with a view to ascertain the best and most economical method of introducing a continuous system of supply. In their final report these officers urged the necessity of a careful test being made of the mains and branches to check the existing waste, the enlargement of the storage capacity at Tallah, and suggested means by which the continuous system might be gradually introduced into the City. They did not approve the Municipal Engineer's recommendation in regard to elevated reservoirs, and were of opinion that the existing pumping power, with slight alterations at two of the power stations, would be found to be sufficient to admit of the conversion of the intermittent into a continuous supply. This report was finally adopted by the Corporation on the 7th May, 1902. The cost of the conversion is estimated at about £100,000.

Steps are now being taken to construct an additional reservoir at Tallah, with a capacity of 5,000,000 gallons, at a cost of £16,520. A supply of waste water and positive water meters have been ordered and a definite area has already been brought under a continuous supply. As there is no apparent hindrance to the work, the system should be extended to the entire city area within the period prescribed in the Act.

Measures have been undertaken also to increase the efficiency of the arrangements at Pulta. The system of sand-washing is being improved and the analysis of water is being carried out in greater detail. The Health Officer reports that the quality of the filtered water compares very favourably with that of the largest towns in Europe. Three new engines are being supplied at a cost of about £15,600. The question is being considered of increasing the number of sand-filters and of more frequently renewing the filter-beds.

In this connection it may be mentioned that a Green's economiser has been erected at Tallah at a cost of £430.

The quantity of filtered water pumped through the mains during the year was 7,457,841,070 gallons, giving a daily average of 20,433,227 gallons, the gross cost per 1,000 gallons being 2·8 annas. The total expenditure debitable against the Water-supply Fund amounted to £93,700. The receipts from the sale of water totalled £11,390, a decrease of about £400 as compared with 1900–01, when a large number of transports for China were supplied with water. The consumption of filtered water per head of the population during 1901–02 was 24·22 gallons per day. The total mileage of filtered water mains and services in both the town and added areas on the 31st March, 1902, was 316·85 miles, the number of standposts in the town area being 955 and in the added area 1,040.

A new steam water-boat has been provided at a cost of £5,500 for the supply of filtered water to ships. The growing demand necessitated this outlay, the old water-boats being insufficient for the work.

Unfiltered supply.—Arrangements are being made to extend the supply during the current year to all the sewered roads throughout the City. The cost is roughly estimated at £38,560 and due provision has been made in the Budget. The supply has been extended for a length of 12,195 feet during the year. The total mileage of unfiltered water pipes on the 31st March, 1902, was 158·15 miles.

The extension of the unfiltered water supply will directly relieve the demands for filtered water in hundreds of privies throughout the town. The cost of this change will fall upon the Corporation and prove beneficial in the saving effected in the use of filtered water.

Suburban drainage.—The Corporation have taken in hand the Suburban Sewerage Scheme, which had made but little progress during the past few years. In 1896 Messrs. Hughes and Kimber submitted, subsequent to the visit of Mr. Baldwin Latham to Calcutta, a Joint Report embracing a scheme for the sewerage of the suburban area, improvements to the town area, Palmer's Bridge Pumping Station and Outfall works. Their recommendations did not agree with those suggested by Mr. Baldwin Latham, but received the general approval of the Government in January, 1897, on the understanding that particular sanction should be obtained for the details of the project on the plans and estimates being worked out. In May, 1901, the sanction of Government was obtained to the works embraced on the Outfall section under Contract II., at a total cost of £196,200. The works completed in whole or part under this sanction include the Town and Suburban Storm-water Channel and Open Sewage Channel, the Town High-Level Sewer and two sluices at Byntolla.

A further reference was made to Mr. Baldwin Latham in January, 1901, and he submitted a report in September, recommending that tidal action should be brought into operation at a point a few yards to the east of the railway line, near the Ballygunge Rifle-range, thereby doing away with the necessity for a pumping station at Ballygunge, the Suburban High-Level Sewer, and the pumping station and sluices at Byntolla. His report was referred to a Sub-Committee of Engineers, who, after carefully considering the subject in consultation with the Chief Engineer of the Corporation, submitted a report in which they declared that the discharge of crude sewage into an open *khal* at the point indicated by Mr. Latham would result in the creation of an intolerable nuisance to the inhabitants of Ballygunge. They therefore urged the necessity of conveying the sewage through a High-Level Sewer to a point 5,000 feet further east, to the junction of the Suburban and the Town High-Level Sewers. The second portion of the scheme, which includes the completion of main sewer No. 1 (from Kidderpur to Ballygunge), the construction of a pumping station at Budge-Budge, a syphon under Tolly's Nullah, a Suburban High-Level Sewer, and a pumping station at Ballygunge, has since been approved and sanctioned by the Government of Bengal.

The Corporation accordingly have decided to complete Main Sewer No. 1 and its outlet as soon as possible, so as to give relief to those residing in the badly-drained tract which it traverses. The sewer is practically complete throughout Kidderpur and Alipur and for the greater part of the distance between Tolly's Nullah and Ballygunge. The construction of the remaining main sewers has been approved by the Corporation and the necessary details are being prepared. Action is being taken by the Engineer's Department for the preparation of a surface drainage scheme for the suburbs and this should be considered by the Corporation during the current year. The lamentable state of the drainage in the suburban area, the unhealthiness of the locality, and the high death-rate, undeniably point to the urgent need for action.

Engineering and Conservancy.—The new District Scheme also came into operation during the year. Under it the Engineering Department has charge of Conservancy, the Health Officer being left to discharge the duties more directly concerning the health of the City. District No. I, which comprises Wards 1 to 6, was equipped on the 1st July, 1901, Mr. W. Johnstone being appointed District Engineer, Dr. R. Sen, District Health Officer, and Babu Abinash Chunder Roy, District Building Surveyor. The district worked satisfactorily, and in December the Commissioners unanimously approved the extension of the scheme to the other portions of the town. Districts II (Wards 7 to 12), III (Wards 13 to 17, inclusive, and 19 and 20) and IV (Wards 18 and 21 to 25 inclusive) were, accordingly, equipped on 1st January, 1902, the District Engineers being Mr. P. B. LePatourel, Babu J. C. Aich, and Mr. A. E. Chapman, respectively. It was considered advisable to give a trial to existing men on the staff of the Corporation in the new offices of District Engineers. The Government of Bengal have lent the Corporation the services of three members of the Subordinate

Medical Service, namely, Messrs. Maloney, Harvey, and Mansfield, for the posts of District Health Officers. The first-named has since been transferred to the Plague Department, and his place has been taken by Mr. P. R. Roy, D.P.H. The establishment of District Offices forms a material part of the scheme. Three of the posts of District Building Surveyors were given to men on the establishment, the services of a qualified Licentiate of Engineering being secured for the fourth vacancy. A complete staff for the discharge of business in the Department of the Engineer, Building Surveyor, and Health Officer, accordingly is engaged at No. 26, Cornwallis Street for District No. I; at No. 118-1, Bow Bazar Street for District II; at No. 1, Municipal Office Street for District III; and at No. 9, Belvedere Road, Alipur for District IV.

The extension of the system to the Departments of the Collector and Assessor is a subject for the future consideration of the Corporation.

The outturn of work in the Engineering Department was less than in the previous year mainly owing to the stoppage of work on the Suburban Drainage Scheme.

The works on hand in the Department constitute a formidable list, and include the following in various stages of execution:—Extension of the continuous water-supply scheme £27,000, extension of the unfiltered water supply to all sewered streets £31,000, construction of a new reservoir at Tallah £16,600, introduction of a new system of sand-washing at the filter-beds £1,650, erection of three new engines at Pultah £20,940, resumption of work in connection with the Suburban Drainage Scheme £93,000, extensive repairs to the two existing Gowkhanas £8,110, and construction of two new ones in Districts Nos. I and IV £16,400, construction of a new Dhobikhana in District No. I £700, the laying out of six new squares £10,900, reconstruction of Tangra Cattle slaughter-house £3,300, and provision of a slaughter-house for goats and sheep in each district, construction of new district office buildings in Districts I and IV £6,700, extensive addition to the Municipal Market £5,300, and construction of a new market in Lansdowne Road £4,700, construction of the new Municipal Office Building £40,900 construction of a new vaccine depôt £2,700, and of four district vaccination stations £1,300, construction of a contagious diseases hospital, erection of a refuse-destructor at Entally £11,600, acquisition and demolition of Ghoomghur Bustee, and the re-construction of roads and buildings in that area £11,700.

The Chairman has reason to believe that the public generally appreciate the District Scheme as it lends itself to greater despatch in business, secures better control, and fixes responsibility on individuals. The ratepayers are now afforded a ready means of representing their complaints in their departments and of obtaining more prompt attention. The four district officers are in telephonic communication with the chairman's office, and the district officers are thus in close touch with the heads of departments.

The effect of the change will not be fully experienced until a staff of qualified men have been secured for the new scheme. Wherever possible, the old hands have been given a trial in the new posts. The scale of salaries under the scheme is sufficiently high to attract competent men, and as vacancies occur in the ranks, better qualified men are being engaged.

Plague.—Plague recrudesced in the middle of January, after the usual quiescent period from June to December. The epidemic followed much the same course through the city as before, attaining a maximum in the first week in April spreading from the central wards towards the north, and afterwards to the southern portions of the town. The beginning of the epidemic was earlier, its growth less rapid, and without reaching the same degree of intensity, its decrease took place at a later date and at a slower rate. The total number of deaths reported during the epidemic in 1902 is shewn as 6,925, as compared with 7,398 in the previous year, attacks during these periods being reported as 7,418 and 8,117 respectively. The disinfection of plague-infected rooms has been persistently carried out with the result that only about half a dozen instances are known of plague recurring in rooms after disinfection. The disinfection of adjoining rooms has been carried out where practicable and with good results. Many disinfections have been done on account of the death of rats, and in many cases human plague has not subsequently appeared at the site.

The plague measures during the period have been extended in the direction of demolishing huts which had proved to be plague-spots and centres of disease. Early in the epidemic a number of most insanitary huts were thus removed in Roop Chand Roy's Street in Ward VII. The plague returns shewed 300 fewer cases in this Ward than in the previous year. A similar remark applies to Ward V where demolition was carried out extensively in Hanspuker Bustee.

Compensation was duly paid to the hut-owners, and the work was carried out with as little inconvenience as possible to the parties. In the majority of cases the owners themselves demolished the structures. The results are very encouraging, and offer hopes of much future success in the work of clearing away insanitary dwellings. The outbreak caused little alarm in the city, and the inhabitants, apparently, are beginning to regard the disease as a normal visitant.

A proposal has been made to amalgamate the Plague Department with the ordinary staff, utilising the services of the Special Plague Medical Officers as District Health Officers. The arrangement has not yet been approved by the Government.

Forty inoculations were performed during the year. The public were left a free choice, opportunities being given to them for inoculation without any pressure for or against the measure.

The actual expenditure during the year 1901–1902 has been £19,800. According to an order of Government the expenses against plague in future will form part of the ordinary expenditure of the Corporation.

Bustee Improvements.—Owing to the failure of the proceedings under Section 400, to secure the necessary improvement, and to the existence of plague in bustee areas, the energies of the Corporation were mainly directed to action under Section 406.

Six bustees are being dealt with under Section 400, in four cases the owners being required to carry out certain prescribed improvements.

Ninety-seven bustees have been taken up for improvement under Section 406, and 27 standard plans have been sanctioned. The improvements prescribed in these plans will secure wide roads, proper drainage and latrine arrangements, and adequate space for ventilation. In seven cases the owners have commenced the prescribed work, and the Corporation are prepared to carry out the necessary improvements in the remainder at the expense of the owners on the failure of the latter to comply with the requirements of the law.

Dwellings for the Working Classes.—The difficulty of designing suitable dwellings for the poor is felt to an exceptional degree in this city. Special objections exist on account of caste and local customs, while, in view of the low cost of rooms in bustees, it is almost impossible to erect buildings of a sanitary class to compete with huts at remunerative prices. An experiment was made during the year by two zemindars, Messrs. Sita Nath and Janaki Nath Roy, in the erection of a block of masonry buildings at a cost of about £3,300, according to the design of the model dwellings of the Bombay Improvement Trust. There appears to be room for many such buildings in Calcutta to supply the wants of clerks, students, and the artizan classes. The measure is specially valuable as an example to land-owners, and an experiment towards the solution of one of the most difficult questions in municipal administration. A less expensive design is required to meet the case of bustee-*wallahs* who are accustomed to pay small fees for shelter in insanitary and overcrowded rooms of huts. The Corporation have sanctioned the acquisition of an unhealthy bustee in Ward No. 10, at a cost of £11,720. In addition to clearing away insanitary dwellings and constructing a highway through the tract, it is hoped that something may be done in the way of erecting model dwellings for those who will be disturbed by the change. Plans for model bustee cottages have been designed. It is proposed to experiment with them in housing the labourers in the employment of the Corporation.

Building Department.—The foundation of the Building Department was a feature in the work of the year. Formerly operations under the Building Regulations had been carried out by the Engineer's Department as a work of secondary importance. As a consequence complaints were general, and little attention was given to the Building Regulations. Four District Building Surveyors have been appointed with the necessary subordinate staff, the Department being directly under the Deputy Chairman.

Cemeteries.—The Health Officer strongly reported against intra-mural burials on account of the danger to the public health, and the Government, on the recommendation of the Chairman issued an Order, in February last, directing the closing of the following cemeteries and burial grounds:—(1), South Park Street Cemetery; (2), North Park Street and Mission Cemetery; (3), Tiretta Cometery; (4), Portuguese Church Cemetery, 15, Portuguese Church Street; (5), Boytakkhana Church Cemetery; (6), Greek Church Cemetery, 8, Amratolla Street; and (7), Mosque Burial-ground, 86, Nimtola Ghât Street.

The Corporation in January, 1902, appointed a Special Committee to enquire into and report upon the arrangements for burying, burning and otherwise disposing of the dead in Calcutta, the Committee being asked to take up the question of the Christian Cemetery on the Circular Road as an urgent matter.

This Committee accordingly recommended that land be acquired for a City Cemetery sufficiently large for the requirements for about 50 years, and that meanwhile an extension of the existing cemetery on the Lower Circular Road be granted to the extent of 10 bighas to supply immediate wants. The Corporation have approved the recommendations of this Committee. Ten bighas of land have been taken up as an extension of the existing cemetery, and a new site, measuring 200 bighas, has been chosen for a new City Cemetery near Jadubpore Police Thana, at a cost of £3,200. Everything possible will be done to suit the convenience of the public in using the new City Cemetery, and negotiations are taking place for the extension of the Electric Tramway service to that place.

During the year the Corporation provided two new burial-grounds for Mahomedans in the north and south of the City, the existing grave-yards being altogether unsuitable. An area of 22 bighas has been acquired accordingly at Bagmari, at a cost of £1,350, and 29 bighas at Gobra, at a cost of £1,610. The sites have been approved of by the Mahomedan Burial Board, and the new burial grounds will supply a long-felt want.

Refuse Destructors.—The use of destructors for the disposal of refuse in Calcutta has received considerable attention during the year. In its present condition the existing incinerator at work in the suburbs would be regarded as a public nuisance in the crowded parts of the town. Elsewhere, the efforts of the Corporation have twice failed to introduce incineration in past years. The Commissioners therefore considered it proper to require that reasonable security should be secured for the proper working of the destructor before undertaking further risk.

After a careful investigation of the subject, the Corporation accepted the offer of Messrs. Joseph Baker & Sons, of London, for the supply of a nine-cell destructor. The apparatus will be erected at Entally, with a capacity for the disposal of all the refuse which at present is conveyed to Platform No. IV, amounting to about 140 tons a day. The plant will cost £770, and if, at the end of eight months' trial (including one wet season), the incinerator fails to prove efficient or is found to be a nuisance, the contractors have guaranteed to refund two-thirds of the total cost. The sanction of Government has been obtained to the project, and the experiment will be carried out in the course of the current year.

The success of this measure will, in all probability, accelerate the removal of the municipal refuse train from the Circular Road. The existence of this train is a grave disfigurement, and checks the development of property in that neighbourhood. The Commissioners await the result of the experiment at Entally before applying the system at several appropriate sites. The establishment of destructors would greatly assist the Conservancy Department.

Slaughter-houses.—The Municipal Saughter-house at Tangra has been placed under the charge of the Market Sub-Committee, and many useful improvements have been suggested by them. The work of re-organisation will be carried out during the current year, the necessary expenditure on buildings being estimated at about £2,300.

The need for cattle slaughter-houses in the south-west suburbs and the north of the town has been brought to notice, and the subject is receiving attention. Meanwhile arrangements are being made to provide a slaughter-house for kids and goats in each district. Illicit slaughtering is common and a want exists for slaughter-houses in sites convenient to the public.

Health Department.—Under the Re-organisation Scheme a fully qualified Medical Officer is stationed in each district as District Health Officer with the needful clerical staff.

Fifteen Sanitary Inspectors are provided on salaries sufficient to attract competent medical men. The original scheme contemplated leaving food inspection in the hands of these officers. Experience, however, has shewn the need for additional attention to this duty, and the Corporation has sanctioned the appointment of a qualified Medical Officer as Food Inspector in each district.

Improvements are in view in the collection of vital statistics in the employment of the Sanitary Staff to check the mortuary returns by local enquiries.

The meteorological changes were not attended by any appreciable effect on the mortality, which, except for the first three months of the year, was below that of the corresponding period of the previous year. The higher mortality of the first quarter was caused by plague, and cannot be associated with the slight changes in meteorological conditions. Apart from an outbreak of small-pox at the same time as the plague epidemic there was no special feature in the vital statistics of the year.

The usual chemical and bacteriological work was carried on chiefly in testing water, ghee, milk, butter, arrowroot, barleypowder. An important judgment was delivered during the year in favour of the Corporation in a prosecution for the adulteration of ghee. The accused was one of the largest wholesale vendors, and the proceedings may be regarded as a valuable test case.

The necessary apparatus for examining the illuminating power of gas was received during the year, and work was carried on accordingly.

The low birth-rate continues to form a prominent feature in the statistics. In the opinion of the Health Officer the cause is largely due to the want of efficient registration. The Committee, when dealing with the Re-organisation of the Health Department, considered that better results might be expected regarding the collection of birth statistics from the services of Hospital Assistants as Vaccinators.

The Health Officer reports the year as comparatively unhealthy, the death-rate, excluding plague, being 28·9 as against a mean of 27·4 per 1,000 during the previous ten years. An epidemic of small-pox accounted for 2,097 deaths, the mortality from cholera and fever being below the average. Including plague, the returns, however, shew an improvement in the public health, the registered death-rate being 38·2 per 1,000 as compared with 43·5 in 1900–01. The Health Officer refers to the occurrence of 30 cases of epidemic dropsy in the month of June, and is unable to account for the appearance of the disease or its sudden disappearance.

Under the Re-organisation Scheme the work of vaccination has been placed in charge of the District Health Officers. A staff of hospital assistants has been provided for the work in place of men possessing no qualification. A female vaccinator has been provided for each district. Arrangements are being made to provide suitable vaccination offices. Owing to irregularities in procuring a supply of lymph the Corporation have decided to establish a special vaccine depôt for its own requirements. Although the arrangements were not complete throughout the year, the results are satisfactory, the number of vaccinations (35,630) being the largest on record, except during a specially severe epidemic in 1895. The number of primary vaccinations (17,820) is the highest on record. The percentage of success in primary cases was 98·3.

The Corporation have decided to establish a vaccine depôt for their supply of lymph. A site has been selected, and plans have been prepared according to modern principles. The Corporation have allotted £2,700 in the Budget for carrying out the work.

The establishment of new vaccination stations has been approved, £1,670 having been sanctioned for the scheme. It is proposed to construct an office in each district, the buildings to be rendered as attractive as possible to the public.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR 1901.

(*Dr. J. Nield Cook.*)

Births.—The birth-rate of the town calculated on the registered births was 10·7 per 1,000 of the population. Judging from towns where the births are better registered than they are in Calcutta I calculate that a normal Indian birth-rate should not be less than 40, making allowance for the fact that in Calcutta the female population is only half the male I estimate the normal birth-rate at 20. If this is anywhere near the correct figure it would appear that nearly half the births escape registration. We have Sub-Registrars sitting in Offices in different parts of the town who register any births of which information is brought to them, but the bulk of the people either don't know anything about it or don't take the trouble to register the births that occur in their families, and we have no efficient system of getting information of these births to enable us to bring pressure to bear on the parents and guardians to register them. I have from time to time recommended the licensing of all practising midwives and requiring them to give information of births. I brought this suggestion up again during the year, but the Commissioners and Government considered it too drastic, so it was not adopted. When this was refused I requested sanction for subordinate officers under the Sub-Registrars to go about the District making inquiries, but this did not meet with the approval of the Commissioners. The want of efficient registration of births makes some of our other statistics unreliable or even misleading, as for instance, the proportion of infants dying under one year of age to every 1,000 births, and throws difficulties in the way of our Vaccinators whose work would be much easier if they had a complete record of all the births that occurred.

Deaths.—The abnormally high death-rate of 38·2 per 1,000 of the population was due to plague. If we eliminate that disturbing factor from the mortality of the year under review and also from the mortality of the previous ten years the death-rate works out at 28·9 against a mean of 27·4. So that if all the plague deaths were registered as such, the year was comparatively a somewhat unhealthy one. This may be attributed to an epidemic of small-pox which accounted for 2,097 deaths, the mortality from cholera and fevers being below the average and that from dysentry and diarrhœa only slightly above it. The epidemic of plague which occurred in the early part of the year will be dealt with separately by the Special Health Officer. Of special diseases influenza was amongst us, but I have no reliable data on which to base a calculation of the extent to which it affected the mortality. I believe that a number of deaths attributed to pneumonia and other diseases of the lungs were primarily due to this cause. A number of cases of cerebro-spinal fever were reported in jails and emigration depôts. 23 deaths were registered under enteric fever, many of the cases being verified by Widal's agglutination test, but the specific bacillus was not found in the town water, and though sanitary defects were present in the surroundings of several of the cases there was no sufficient evidence to establish with anything like certainty the source of the infection. In June about thirty cases of epidemic dropsy, similar in all respects to those formerly described by Col. Kenneth McLeod, I. M. S., occurred in the town. Eleven of the cases occurred in a native college for ladies. The first case was a matron who had returned five days before from a holiday at Nuddea. I wrote to the Civil Surgeon who replied that no case of the disease had occurred there. All the sanitary arrangements of the college were good, and the pupils were well nourished. I am unable to account for the appearance of the disease, or its rapid disappearance which was contrary to precedent. No cases ended fatally.

The following statement shows the mortality from the principal diseases in 1901 compared with the average of the previous five years.

1. No. of Wards.	2. Names of Wards.	3. Population according to Census of 1901.	4. Cholera.	5. Small-pox.	6. Fever.	7. Dysentery and Diarrhœa.	8. Plague.	9. Injury. Suicide. Male.	Suicide. Female.	Wounds and Accidents.	Snake-bite or by Wild Beasts.	Total.	10. All other Causes.	11. Total Deaths from all Causes.	12. Ratio of Deaths per 1,000 of Population. Cholera.	Small-pox.	Fever.	Dysentery and Diarrhœa.	Plague.	Injury.	All other Causes.	From all Causes. For the Year.	Mean of previous Five Years.

Vaccination.—Under the new system of work introduced by the formation of four Districts into which Calcutta is now divided the Vaccination Department has been abolished. The old Vaccinators have been replaced by Hospital Assistants placed directly under the District Health Officers. The post of the Deputy Superintendent of Vaccination has, therefore, been abolished. The total number of vaccinations done during the year was 35,630 the largest number that has ever been done in Calcutta except in 1895, when a severe epidemic of small-pox occurred. The number of primary vaccinations was 17,820 of which 16,899 were children. This is the largest number of primary vaccinations done in Calcutta in any year. The number of primary vaccinations is considerably larger than the number of births registered in the town. The number of births registered was 9,129. I have estimated this at half the true figure. If this is correct 17,820 primary vaccinations were done to 18,358 births which leaves only 538 unprotected. The percentage of success in primary vaccination excluding the unknown was 98·3. The percentage of success in re-vaccination was 51·8. For some time past we have been dissatisfied with the supply of operated calves and preserved lymph by the Government Animal Vaccine Depôt. So I made proposals to the Commissioners to construct a depôt of their own on approved modern principles. This received sanction. A site has been selected, and plans drawn up by the Engineer in consultation with myself, and £2,700 have been budgeted for carrying out the work which I hope to see completed in the next six months. One of my proposals for improving vaccination in the town was to have good district Vaccination Depôts that would be attractive to the public, —a pagoda with a broad verandah where the people could wait with a space round with a few plants. This received the approval of Government, and the Commissioners budgeted £1,670 for the purpose. I have recommended some sites and expect that a start will soon be made.

Filtered Water Supply.—Regularly every week two samples of filtered-water as delivered from the taps were examined both chemically and bacteriologically, and the results submitted to the General Committee as required under Section 243 of the Act III (B. C.) of 1899. The chemical examination showed that as regards "total solids" the amount during the dry seasons was very much higher than what it was during the rains and the subsequent months. The water was found to be free both from "nitrates" and "free ammonia" all throughout the year ; while albuminoid ammonia" averaged 0·0049 part per 100,000. The amount of "chlorine" as dissolved chlorides and of "oxygen consumed" varied from 0·5 to 2·6 parts and 0·006 to 0·018 part, respectively. While "nitrates" in the water averaged 0·020 part per 100,000. Thus chemically considered, the water may be pronounced a good potable water ; the bacteriological examination showed that the number of colonies in agar-plates kept for three days at 37° C never exceeded 100 per C. C. In none of the weekly examinations, comma bacilli nor B. typhi abdominalis, were detected, but B. coli communis were found in all the examinations. With a view to improvement in the better filtration of water in the filter beds at Pultah the Commissioners wanted to examine the water as it is filtered out and collected in the filter wells bacteriologically. The examinations are being made regularly every week, and excepting in a few instances the result of weekly examinations of the bacterial colonies showed that the 36 filter beds at Pultah were acting satisfactorily. Besides the filtered water 51 samples of Hooghli river water and 50 samples after settling were analysed as also 65 samples from tanks and wells. Excepting three, the tanks and wells were all found to be unfit for any domestic use, so they were ordered to be filled up. Altogether 210 samples of water were examined bacteriologically, in connection with local outbreaks of cholera, and comma bacilli were detected in 7 samples of tank water. Guards were posted over these tanks to prevent the spread of the disease by the water being further used, and generally this course with disinfection of infected clothes, etc., checked the dissemination effectively.

Other Chemical and Bacteriological Work.—One hundred and seventy-seven samples of ghee 102 samples of milk, 11 of butter, 8 of flour, 8 of barley-powder, 17 of arrowroot, 8 of disinfectants, 2 of ærated water, 3 of ale, 1 of cornflour, 1 of common salt, 1 of infant's food, and 4 of a miscellaneous nature were analysed ; of these 89 samples of ghee, 77 of milk, 2 of barley-powder, 14 of arrowroot, 1 of corn-flour were found to be adulterated.

The town gas was examined as to the pressure, and it was found to be 8-10ths of an inch. The necessary apparatus for the testing of the illuminating power having been received during October, the examination was commenced in November and the illuminating power of the gas was found to average 16 candles. The gas was found to be free

from sulphuretted hydrogen. Under the present contract, all the street lamps are to be supplied with Welsbach's incandescent burners which would necessarily improve materially the illumination of the town.

13 dead rats sent by the Plague Department were examined, in 8 of these plague bacilli were found, in 2 B. Anthracis and in 3 an animal parasite somewhat like that of surra were found. 13 specimens of blood were examined for enteric fever by Widal's test, and in 4 positive reactions were obtained. Three specimens of sputum were examined, in one *plague bacilli* and in another *tubercle bacilli* were detected. In a sample of intestinal secretion from a suspected tubercular case, no tubercle bacilli were found, and a smear preparation from an enlarged gland in a suspected case of supposed *pestis ambulans* showed no plague bacilli.

The Analyst attended in Court to give evidence in prosecution cases on 66 occasions during the year. In this connection it should be recorded that an important judgment was delivered in favour of the Corporation by the Municipal Magistrate, Calcutta, in the ghee prosecution case (Corporation *vs.* Satyapriya Koch and another) in which the Corporation Analyst pronounced the ghee to be adulterated, while the Chemical Examiner to the Government of Bengal declared the same to be free from any admixture. This may be regarded as a test case, as the accused was one of the largest wholesale vendors and was defended regardless of cost.

Work done by the Sanitary Inspectors.—4,653 cases of disease were investigated, and the number of houses disinfected during the year was 3,787. In addition to these disinfections a large quantity of infected articles were destroyed ; besides articles of clothing, bedding, &c., which were passed through the Equifex Steam-Stove.

ABSTRACT OF THE REPORT OF THE MADRAS MUNICIPALITY FOR 1901-02.

(*Lieutenant-Colonel Sir G. M. J. Moore, Kt., C.I.E.; President.*)

Drainage.—The expenditure on new works amounted to £16,330, the bulk of which was incurred on the new drainage scheme. The work in laying the cast-iron main was continued during the year and 16,824 lineal feet were laid. The laying of the stoneware sewers in Hall's Parcherry, Boodhi Begum's Parcherry, and Azeez-ul-Mulk's Parcherry, in connection with the Ice House Road main, together with the house connections and sewer ventilators was commenced and completed during the year.

Sixty-three house connections and 430 ventilators were fixed in the 7th Division.

At Purasawakam a new sewer of 12-inch and 9-inch cement pipes was laid along the High Road from Vedavinoyagar Road to Saravanaperumal Covil Street—the 12-inch substituting a 9-inch sewer laid in 1896 as a temporary measure. This sewer now takes off the sewage that hitherto flowed into a tank in the latter street.

The opening out of a new street from the Wallajah Road through Chetty's Gardens to Pycroft's Road in Triplicane, and another from Waller's Road through Narasingapuram to the Napier Park is in progress. The buildings acquired through the Collector of Madras, and which are being removed, cost £3,560. Some of this outlay is being recovered by sale of material and portions of land not required. These new streets are being opened for a double purpose, one being to open up the crowded and badly arranged portions of Triplicane and Narasingapuram, and the other to give a clear line for the laying down of the main sewers of the new drainage system for this locality,

Plans, sections, and estimates are under preparation for draining the 5th Division and a portion of the 4th Division, levels having been previously taken for this purpose. Levels have been taken for similar work to be done in the 1st Division.

Sewer No. 3.—After the opening of the joint beach station on the North Beach Road, the municipality has found it very difficult to clean the sewer at the manholes which are now situated between the lines of both the Madras and South Indian Railways, and after much correspondence on this matter, the Consulting Engineer for Railways agreed to recommend that these railways pay for the construction of a new sewer outside their limits in substitution of the one now in use. The Government in their order No. 1573 Ry. of the 20th September, 1901, sanctioned the work being done at the cost of both railways, and the work was put in hand on the 27th January, 1902, and is still in progress. Much difficulty has been met with in carrying out this work, owing to the presence of the old sea wall, with its revetment, having been found on the proposed alignment of the new sewer. Up to date 471 feet of the sewer has been laid.

Water Supply.—The meters referred to in last year's report have been received and fixed in places where they were found necessary. Out of the other 12 works shown in Statement II-A, Appendix I, seven were completed, two are in progress, and the remaining three not commenced, owing to the question raised by Government regarding the grant of 1½ lakhs for plague charges being still under consideration.

During the year under report 1,019 yards of new pipes were laid and 10 fountains, one valve, 12 stop-cocks, seven hydrants, and 56 meters were fixed.

Cleaning Pipes.—From the balance available out of the grant of £8,701, which was provided for cleaning pipes 9-inch and below, £3,200 were spent during the year, and the total length of pipes taken up, cleaned, and relaid during the year was 174,594 feet. This brings the total length taken up, cleaned, and relaid since 26th September, 1900, to 281,538 feet.

On the 1st April, 1901, the level of the Red Hills Lake stood at 35·73, and on the 31st March, 1902, at 40·40. On the 2nd April, 1901, the level of the lake fell to 35·68 when pumping had to be taken in hand for the water supply of the city and was maintained up to 13th November, 1901, when the level of the lake was raised by rainfall and pumping stopped. The lowest level to which the lake fell during the year was 29·07, the level it stood at on the 25th October, 1901.

The quantity of water supplied to the city during 1901-02 was 588,280,185 cubic feet, against 534,865,815 cubic feet last year.

Private Services.—820 new services were laid by licensed plumbers during the year, and 1,610 existing services were extended. The number of new services laid, together with the total up to the end of 1900-01 makes the total of 17,124.

The quantity of water used for non-domestic purposes during the year was 106,416,865 gallons.

Births and Deaths.—The total number of births registered during the year 1901, exclusive of still-births, was 18,872, against 20,672, being 1,800 births less than the year previous, but 461 births above the mean of the decade, viz., 18,411·2. The ratio per 1,000 per annum calculated on census population of 1901 was 37·0, against 40·5. The number of births recorded during the previous year was exceptionally high. The male live-births numbered 9,555 and the female 9,317, the proportion of males to every 100 females being 102·5.

Mortality.—The year under report was a very unhealthy one, and the death-rate all through the year was above the average. The total number of deaths registered during the year was 28,031, against 20,937 of the previous year. The death-rate, calculated on the census population of 1901, was 55·0 per 1,000 per annum, against 41·1 for the year 1900 calculated on the same census population. August and September were as usual the most unhealthy months of the year when the appallingly high death-rates of 89·4 and 84·3 respectively per 1,000 per annum were recorded. It is impossible to say with any amount of accuracy, in the present state of matters in the city, what caused this very high death-rate. Cholera prevailed epidemically from the beginning of August to the middle of November, but the number of deaths returned under this head were not sufficient to account for the increased death-rate. The means at present at the disposal of the Health Officer are not sufficient to enable him to arrive at any conclusion in a matter like this. All the houses where deaths occurred were visited by the sanitary staff and inquiries made, but the lack of medical knowledge on their part, coupled with obtuseness and an overwhelming tendency on the part of the relatives to return negative answers to all questions, prevented satisfactory evidence being obtained as to the exact cause of death. Employing the few resources at disposal, the only conclusion that could be arrived at was that cholera was much more prevalent than would appear from the published figures, and would in itself account for a good part of the excess. In addition, the season appeared to be unusually unfavourable, and many deaths were attributed to fever and dysentery. The scarcity from which, in common with other parts of India, Madras suffered for the last two years, continued to lower the general vitality of the masses of the population, who were in the best of times poor, and laid them open to the ravages of all diseases and particularly of the infectious ones. There was besides a large influx of beggars and semi-starved people from the neighbouring districts where scarcity was much more severe. Many of them either could not or would not work, and either succumbed to some slight indisposition which would scarcely have been fatal to a vigorous individual or actually died of starvation.

Mortality according to Sex.—The male deaths numbered 13,988 and the females 14,043, giving a proportion of 99·6 males to every 100 females.

Mortality according to Nationality.—The deaths among Europeans were 125, among Eurasians 492, among Native Christians 1,075, among Hindus 23,272, among Mahomedans 3,066, and among others 1, the ratios being 40·3 among Christians, 56·6 among Hindus, 53·4 among Mahomedans, and 2·4 among others, against 35·7, 47·8, 43·7, and 8·4 of the previous year respectively. The proportion of males to every 100 females among Christians was 80·9, among Hindus, 101·5, and among Mahomedans 96·5.

Mortality according to Causes.—There has been a perceptible increase of deaths during the year under all the principal heads of diseases except under measles which

has decreased from 280 to 222. Deaths from fever rose from 5,898 in 1900 to 9,151 in 1901, small-pox from 46 to 292, bowel complaints from 3,408 to 4,870 from cholera, 632 to 1,242, and all other diseases from 10,669 to 12,251. Cholera was epidemic during the second half of the year, and it is probable that a large number of deaths from this cause were registered under the other heads to prevent alarm or to avoid municipal visitations.

Small-pox.—The total number of deaths registered from small-pox was 292 against 46 in the previous year and was the highest number recorded in the decennium, the ratio being 0·5 against 0·1. The usual measures were adopted to check the progress of the disease. Vaccination was vigorously pushed on, houses of the patients including bedding and clothes were promptly disinfected, and, in several cases, patients who had insufficient accommodation were sent to hospitals.

Vaccination.—The total number of cases vaccinated during the official year 1901–02 was 38,265 against 32,571 in 1900–01, the increase being due to the prevalence of small-pox in the city and to the increase in the number of emigrant coolies vaccinated during the year. The results of 38,265 vaccinations performed were 30,064 successful, 4,077 unsuccessful, and 4,124 unknown.

Of the total 34,504 cases vaccinated in the municipal vaccine depôts, 11,337 cases were brought to the depôts for inspection of results, and in 20,918 cases the results were verified by the respective divisional vaccinators. The parents and guardians who failed to comply with the byelaw 5 were warned to take their children to the depôts. In 200 cases the defaulters were prosecuted and fined to the extent of Rs. 79–12–0. The number of cases verified by the inspecting staff was 15,746 out of a total of 34,504.

The percentage of success obtained both in primary and re-vaccinations, excluding the unknown cases from the total, was 88·05 which is 3·64 per cent. below that of the year 1900–01. This decrease is due to the low percentage of success obtained in the Natal Emigration Depôt from the use of the lanoline vaccine as shown below :—

——	Total cases vaccinated.	Percentage of success.
Calf-to-Arm Vaccination	33,078	89·34
Glycerinated lymph	1,426	97·19
Lanoline lymph	3,761	72·88

Out of 38,265 cases vaccinated 21,823 were primary vaccinations, against 19,875 in 1900–01, showing an increase of 1,948 cases with ·35 per cent. of success in excess of the previous year.

During the year 15,610 children under one year of age were vaccinated, including the 66 cases which were done in the Natal Emigration Depôt, against 13,687 in 1900–01. The increase was mainly due to making up the arrears of cases pending ; the percentage of success obtained in infant vaccination was 98·94 which is ·64 less than the previous year. 10,492 of these cases were born in Madras and 5,118 were born up-country.

Small-pox was prevalent throughout the year 1901–02. There was a large number of deaths during the first half of the year and the disease showed a tendency to decline in the second half. Two temporary vaccinators were entertained from May to August 1901 to make house to house inspection. There were also cases of small-pox imported into the city from time to time. Every attempt was made to remove the patients who were insufficiently accommodated to hospitals and isolation camps. The infected houses were disinfected by the sanitary staff and the surrounding localties were visited by the vaccine staff and steps were taken to vaccinate the unprotected children. Re-vaccination was also encouraged.

Fevers.—The deaths from fevers during the year numbered 9,151 against 5,898, the ratio being 17·9 against 13·0 in the previous year. The number registered during the year is the highest ever recorded in Madras. It is impossible to say how many of these deaths were due to malaria, for it must be remembered that fever is a generic term

to the Madrassi, under which every disease attended with fever is included. But whatever the nature of these fevers there is no doubt that the heavy mortality was largely determined by the insanitary conditions which obtain in Madras, viz., overcrowded and ill-ventilated houses in undrained areas together with an insufficiency of food.

Bowel-complaints.—The mortality from dysentery and diarrhœa was 4,099 and 771 respectively against 2,842 and 566 in the previous year. The increase of deaths under these two diseases have been a usual accompaniment to an epidemic of cholera. The ratio of deaths from dysentery was 8·0 per 1,000 and from diarrhœa 1·5.

Infantile Mortality.—The death-rate among infants under one year of age was 328·3 per 1,000 births against 272·0 of the previous year, but the ratio calculated on the total infantile population of 1901 census was 454·0 against 411·5. The scarcity which was prevailing in the city was probably one of the causes of this increase.

Meteorological Conditions.—The following is taken from the report of the Government astronomer :—Temperature was above the average for every month except December when it was 0·2° F. below ; the highest shade temperature was 108·5° F. on the 4th June, and the lowest 59·5° F. on the 26th November. The excess of the mean temperature was greatest in February, and it averaged 3·7° F. " Humidity was below the average for March, equal to the average for May and June, and above the average for all other months. Humidity was lowest on the 23rd May when it averaged 31." " Rainfall was below the average for January, March, April, May, June, September and October, and above the average for the remaining months. The deficiency was greatest for May (2·06 inches) and the excess was greatest for December for which month it was 8·87 inches. The rainfall for the year was 10·82 inches above the average, the total fall being 59·84 inches."

Cholera.—In the year 1900 cholera was epidemic in Madras from the beginning of August to the middle of November. The disease, however, never entirely disappeared from the city throughout the year. Sporadic cases continued to occur in November and December, and in the latter month alone 31 deaths were reported from all parts of the city. It is interesting to compare the course of the cholera outbreak in the city in the last two years. The disease ran identically the same course almost in every detail. The disease was prevalent throughout the year in both the years and assumed epidemic proportions from August to November—but the epidemic of 1901 spread over a much wider area, and consequently the number of attacks and deaths were very nearly double that of the previous year. The next noticeable feature of the two outbreaks is that the greatest number of attacks occurred exactly at the same period of the year almost to a day, namely, from the 16th August to 20th September. It more than ever proves the close relationship the epidemic bears to seasonal influences. In another part of this report reference was made as to the causes of increased mortality of the year. Every one of those causes operated favourably to the outbreak and spread of the disease.

In common with the city all the neighbouring villages also suffered from cholera. It has always been a point of discussion whether these villages were the means of introducing cholera into the city or *vice versâ*. Suffice it to say that the relation between the two is so intimate that one cannot have an epidemic outbreak with the other escaping. The residents of neighbouring villages—practically all of them—find their work in the city. Any measure, therefore, for the prevention of an epidemic in the city would be insufficient if it does not include means to prevent the spread of the same in these villages.

The total number of deaths from cholera during the year was 1,242, giving a ratio of 2·4 per 1,000 of the population. This is the highest recorded in the decennium. The epidemic was worst in the 1st Division, which includes some of the filthiest spots in the whole city. The 5th Division was the next worst centre. A very fair number of cases in this division occurred among respectable Eurasian residents.

Plague measures.—The Passport offices and prosecutions were in charge of the Plague Officer throughout the official year. Passports were issued at Perambore and Bezwada, and those issued at the latter place were checked at Washermanpet. The number of persons detained during the year at the Plague camps were 1,056 at Perambore and 11 at Washermanpet. Besides these, 82 persons were kept under observation at the Egmore Plague Hospital. Five cases of plague were treated in the Egmore Plague Hospital, two died and three recovered. All the cases were imported ones.

During the year under report the total number of passports issued at Perambore to passengers coming from infected areas was 55,120 against 48,019 of the previous year, an increase of 7,101. This increase was owing to a large number of persons leaving those places where plague was severe, such as Vaniyambadi, Ambur and Bellary. The passports dealt with by the Plague Inspection of the city, exclusive of those sent to the medical officers of hospitals, regiments, &c., were 50,171 against 45,469 in the preceding official year. The number untraced by the city passport examiners was 1,224 against 1,146 in 1900–01. The percentage of untraced passport holders was 2·44 against 2·52 of the preceding year. Besides those issued in the city, passports were also received from mofussil stations. These mofussil passport holders who were also observed in the city numbered 8,079 against 3,593 of the preceding year, showing an enormous increase of 4,486. Out of these the number of passport holders left untraced and unobserved was 516 against 365, an increase of 151, but the percentage of such untraced cases was only 6·39 against 10·16 in the preceding year, a decrease of 3·77.

The attendance of the passport holders was very satisfactory throughout the year. Amongst the 50,171 passport holders there were only 339 prosecutions and 178 convictions against 45,469 passport holders, 546 prosecutions and 302 convictions in 1900–01, and the fines inflicted amounted to Rs. 591-12-0 against Rs. 893-12-0 in the previous year.

The Port Health Officer reports as follows for the calendar year 1901 :—433 vessels, departures from Madras, carrying a crew of 36,527 men with 34,312 passengers were inspected and granted bills of health. 188 vessels, arrivals from plague infected ports, carrying a crew of 16,396 men and 4,589 passengers for Madras were inspected before any communication between the vessels and the shore was permitted, and all the passengers were given plague passports. 12,000 shore coolies who worked on board these vessels were inspected before they were sent on board and were given a disinfecting bath on their return in the evening. Some of these coolies, from sickness or other causes, were necessarily absent at times. These were traced out and inspected by the municipal staff.

ABSTRACT OF THE REPORT OF THE MUNICIPAL COMMISSIONER FOR THE CITY OF BOMBAY FOR 1901-02.

(*W. L. Harvey, Esq., C.I.E., Municipal Commissioner.*)

PUBLIC WORKS.—*Drainage.*—The machinery at the compressor station and the several ejector stations worked satisfactorily during the year.

The engines and pumps at the Love Grove pumping station worked satisfactorily. The efficiency of the pumps as tested by monthly observations taken showed an average of 89·92 per cent.

The street portions of the house drainage connections, carried out partly by contractors and partly departmentally, numbered 4,132, at a cost of £6,811.

Several latrines and urinals have been constructed at different places to meet the public convenience.

Works in connection with the sanitary arrangements of the various health camps, observation camps and plague hospitals, were carried out by the Drainage Department, Ordinary Branch. Several important works were also executed by the Drainage Department, Special and Ordinary Branches.

WATER WORKS.—*Tansa Lake.*—The rainfall for 1901 was 96·15 inches against 104·60 inches for 1900. The total quantity of water received in the lake was 35,054 millions of gallons, or 47·8 per cent. of the rainfall on the catchment area of 52·5 square miles. On the morning of the 29th November, 1901, the Tansa Duct gave way at mile 22-2530. The supply was temporarily restored on the 4th December, and water was again turned on in the duct on the 25th December, 1901. The stoppage of the supply while repairs were in progress was taken advantage of to repair the duct between Bhandup and Thana. During the year there was no burst in the 48-inch main. Most of the remaining jungle along the line of the aqueduct in the Kasheli Division has been cleared.

Vehar Lake.—The rainfall for 1901 was 75·58 inches against 72·96 inches for 1900. The total quantity of rain which fell on the whole drainage area of 3,900 acres was about 6,650 million gallons, of which about 5,053 million gallons reached the lake, or about 76 per cent. of the total rainfall. There was no burst outside Bombay on the Vehar 24-inch main, but there were two bursts near Coorla on the 32-inch main.

Tulsi Lake.—The rainfall for 1901 was 93·62 inches against 93·02 inches for 1900. The total quantity of rainfall on the whole drainage area of 1,700 acres was 3,611 million gallons, of which about 2,329 million gallons reached the lake—this forms 64·5 per cent. of the total rainfall. There were three bursts on the Tulsi line, two of which were due to the action of the scraper which was passed through the main in February, and which in addition to improving the quality of the water has increased the total delivery by about 12½ per cent.

Supply and Distribution.—A 4-inch main was laid to supply new buildings erected on the Improvement Trust Wellington Lines Estate. There were 223 bursts in several mains, 431 new connections were made and 273 connections were cut off for various reasons. The total number of connections is 20,552.

PUBLIC HEALTH.—The state of the public health during the year was better than in the preceding year, the number of deaths, exclusive of still-born, being 59,495 against 79,350 for the previous year. There were 18,736 deaths from plague against 13,285 during the preceding year. The control of plague measures was transferred to the Health Department in October 1901. The number of births registered during the year was 13,520.

The water-supply was analysed by Dr. Cayley chemically and bacteriologically every month during the year.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF BOMBAY CITY FOR 1901.

(*Dr. John A. Turner.*)

In reviewing the history of the health of the City during the year 1901, it is necessary to consider the hygienic aspect apart from Plague. The City of Bombay is situated on an area which formerly consisted of a group of small islands which have gradually become one by the extension of the layer by reclamation and filling in of the landlocked space of seas. The area of the island is 22·41 square miles. The configuration of the island is made up of two parallel ridges of hills, the space between forming a basin, which in parts is below the level of high water mark. This configuration must be considered in dealing with the hygienic aspects as in times of rain parts of the Island are flooded.

The dampness of the soil contributes a great factor in the health condition of a community, and every precaution should be taken to dry the soil by drainage and preventing the storm water from the high levels flooding the lower levels. Owing to this peculiar configuration much difficulty is experienced in draining the low-lying parts, but every attempt should be made to prevent further access of water by diverting all sewage and surface water directly away from houses in proper channels and cementing the surface of the ground around houses, stables and washing places.

Much interesting information is supply by the Government Meteorological Observatory. Great fluctuations are to be noticed in the rainfall in the observations taken in various parts of Bombay. Rainfall during 1901 was 75·32 inches. This was not spread all over the rainy season, but ceased earlier than usual. A large portion of this rain flows off the surface, some remains on the low-lying land, a portion percolates the soil to increase the ground water, some is used up by vegetation, while the remainder evaporates. The influences at work, which affect the health of the people, are evaporation, condensation and percolation.

Temperature, Pressure and Humidity.—The chief of these is the percolation through the soil to increase the ground water. The most unhealthy places are those in which the ground water is highest and those that are liable to fluctuations, as in addition to the ground water always present, the low-lying parts of Bombay received polluted water from the higher levels. The raising of these parts by filling in does not reduce the height of the ground water, but increases it in that locality unless provision is made for drainage before filling in. Increase in sickness during and immediately after the rains is chiefly due to the dampness of the soil and moisture of the atmosphere around dwellings; as the ground water rises after heavy rains, the polluted ground air is forced out into houses. In most of the houses of the poorer classes the floors are of mud and cowdung, and the people sleep on the ground. Diseases, of the lungs, rheumatism and malaria are the results. Improvement in the general health of a locality has always been found to follow draining of the soil

As regards the seasonal influence on diseases, the cold weather season, extending from December until March, is the period of highest mortality, the hot weather from March until June the lowest, and from June until November the period of seasonal increase in the mortality.

The low vitality of the poorer classes of Hindus renders them easily susceptible to seasonal influence. Apart from plague, which has its periodical rise in the cold weather months, diseases of the respiratory system play great havoc among the poorer classes. In the cold weather, when they are obliged to sleep indoors in an overcrowded and vitiated atmosphere, plague spreads rapidly, while the cold air easily affects them when

exposed to it, causing chill and disease of the respiratory system. The improvement in the health of the people is very noticeable when they vacate their houses for well ventilated camps.

Population.—The population of the city estimated by the census of 1901 was 776,006, and it is on this population that all the statistics except those of age-periods are based, as the information regarding the population by age-periods adopted in the last census was not available in time.

Births.—The number of births registered during the year was 13,520, being 832 more than in the previous year, and 1,656 more than the average of the preceding five years, giving a birth-rate of 17·42 per 1,000 of population.

In my report for the last year, I alluded to the difficulties in obtaining an accurate return of the births in the city. In this year's report I state what has been done to improve the system of birth and death registration. According to the census returns there were 171,122 females between the ages of 15 to 45. The proportion of males to females was 161·96 to 100. The number of births registered was, however, 832 more than last year. Of the total number of births 7,085 were males and 6,435 females; and 2,153 still-born births were registered during the year under report. Birth-rate amongst Parsees is a little higher and that amongst Europeans a little lower than in the previous year.

Mortality.—The number of deaths in the City of Bombay during 1901, exclusive of still-born, was 59,495, being 19,855 less than 1900, but 5,677 more than the average for the past five years, giving an annual death-rate of 76·66 per 1,000 of the population.

The death-rate from all causes during the past 11 years was—

Year.	Death-rate.	Year.	Death-rate.	Year.	Death-rate.
1891	29·01	1895	30·52	1899	68·07
1892	32·26	1896	40·71	1900	96·56
1893	28·16	1897	58·28	1901	76·66
1894	53·25	1898	63·23		

Plague.—During the greater part of the year, the control of all plague measures was under Government as in the previous year. In October I took over the duties of supervision in addition to my own, and the control of plague is now in the hands of the Health Department.

I will allude here briefly to the plague epidemic during 1901. The mortality from plague began its seasonal rise in December, 1900, and reached its maximum in February, 1901, and then declined. There were 21,006 attacks and 18,736 deaths from plague during the year as against 17,913 attacks and 13,285 deaths during the last year. As in previous years the general Hindu community suffered severely, the mortality amongst this class being 12,418 as against 9,030 during the last year. There was also an increase in the number of deaths from plague in all the communities except Europeans, who show 10 cases as against 11 of the last year. There was a marked reduction in the number of deaths occurring in Upper Colaba, Esplanade, Chaupati, Walkeshwar and Tarwari as compared with the last year. The increase in Mahim is, no doubt, due to the movement of the population there.

A total of 12,611 deaths from plague occurred amongst males and 6,125 amongst females. The age-period of males was from 14 to 44 years and amongst females from 10 to 34 years, the highest mortality occurred.

The highest total mortality was recorded in the month of March, the number being 4,697, February coming next with 3,850 deaths; the lowest mortality was in June, 312 deaths being recorded. From June the mortality rose gradually to the end of the year, 732 deaths being recorded in December. The plague mortality was highest on the 26th February, 214 deaths being registered, while on the 25th February the highest daily mortality for the year was recorded, viz., 409.

The measures adopted for controlling plague were the provision of camps for those willing to evacuate plague-stricken houses, disinfection by washing the rooms with

perchloride of mercury and phenyle and fumigation with sulphur. Compulsory removal to hospital was not enforced. The disease was of a very virulent type, the mortality in hospitals varying from 79 to 91 per cent.

After all has been said and written, about plague, it will not be necessary for me to enter into the subject. I must, however, mention that from the experience gained during the past years in preventive treatment of this disease the overcrowding, poverty and insanitary condition contribute largely to its spread. Nothing can be more evident than that fresh air, sunlight and improved sanitary surroundings are antagonistic to the spread of the disease. Over 13,000 persons were received in the municipal camps during the plague epidemic of 1901. The percentage of deaths in these camps was 0·56. About 25,000 people removed of their own accord into the private camps on the sea-face and in the north of the island.

Causes of Deaths compared.—In the following table it will be observed that there has been a marked decrease in the number of deaths from all diseases except plague, which stood highest amongst them when compared with the figures of the previous year.

TABLE SHOWING THE NUMBER OF DEATHS AND THE DEATH-RATE FROM DIFFERENT CAUSES IN 1900 AND 1901.

Cause of Death.	1900.		1901.	
	Number of Deaths.	Death-rate per 1,000 of Population according to the Census of 1891.	Number of Deaths.	Death-rate per 1,000 of Population according to the Census of 1901.
Small-pox	3,018	3·67	159	·20
Measles	1,500	1·82	67	·08
Fevers	7,928	9·64	7,921	10·20
Cholera	4,273	5·19	198	·25
Plague	13,285	16·16	18,736	24·14
Phthisis	8,199	9·97	6,516	8·39
Diseases of the Nervous System	4,328	5·26	2,971	3·82
„ Respiratory System	12,522	15·23	7,804	10·05
Diarrhœa	5,850	7·11	2,375	3·06
Dysentery	2,826	3·45	1,341	1·72
Accidents	1,072	1·30	764	·98
All other Causes except Still-born	14,549	17·70	10,643	13·71
Total	79,350	96·56	59,495	76·66

By sexes, 35,504 males and 23,991 females died during the year. Excluding those under five years, the highest number of deaths amongst males occurred in the age-period between 25 and 29 years, 4,286 deaths having been registered; and amongst females 3,145 in the age-period of 60 and over.

Amongst persons born in Bombay, 13,064 deaths were registered during the year and amongst those born outside of Bombay, 44,355. The places of birth of 2,076 persons could not be ascertained.

The Death-rate by Caste.—The Jain community, which includes Banias, excepting Negro-Africans, Buddhists and Lingaets, who form very small communities, show the highest mortality, viz., 152·86 per 1,000 of population. Next comes Hindus, low-caste, the death-rate being 87·56. The general mass of the Hindu community give a death-rate of 85·42, and Mussalman, 71·43. The death-rate amongst Parsis was 30·54, European death-rate being much lower than the last year.

Small-pox.—From small-pox 159 deaths occurred during the year, as compared with 3,018 in 1900. The disease did not assume an epidemic form.

Cholera—From cholera 198 deaths were registered during the year as compared with 4,273 deaths in 1900. The disease did not assume an epidemic form. The highest number of deaths from this disease was registered in the month of August. Of the total number of deaths 131 occurred amongst Hindus of other caste, and 28 amongst Hindus, low-caste, and 18 amongst Mussulmans. A total of 36 deaths occurred amongst persons who had resided in Bombay for three months and under, and 21 deaths amongst those who resided in Bombay for six months and under. The greater number of deaths occurred in persons born outside of Bombay.

Fevers.—A total of 7,921 deaths was registered from fevers. Remittent fever claims the highest number, *viz.*, 7,266, being 12 less than last year, and 1,476 more than the average of the previous five years. To simple continued fever 113 deaths were ascribed, being 68 more than last year, and 368 less than the average of the previous five years. To enteric fever 62 deaths were registered, being two more than the last year and 20 more than the average of the last five years. To ague 480 deaths were ascribed, being 65 less than the last year, and 227 more than the average of the last five years. Out of the large number of deaths returned as due to remittent fever many may have been due to relapsing fever and plague, as it is very difficult to diagnose the disease without strict examination being held in each case. It will be observed that the fever rose and fell with the mortality from plague. It rose from January to March, when 1,310 deaths were registered. The highest number of plague deaths registered in the month of March was 4,697. From the month of April fevers gradually decreased till the end of the year.

Excluding Jains, which form a very small community, there was a slight increase amongst the Hindus of other castes, the rate being 13·42 as against 10·10 in the previous year. A great decrease is noticeable amongst Hindu low-castes, the rate being 9·57 as against 22·18 in the previous year. Mussulmans gives a death-rate of 6·60 as against 9·17 of the previous year.

To relapsing fever 1,560 deaths were due, being 466 more than in the previous year. The highest number of deaths from relapsing fever were registered in the month of May, when 220 deaths were registered. From October the disease decreased gradually till the end of the year.

Measles.—Sixty-seven deaths were registered from this disease, being 1,433 less than in the last year and 777 less than the average of the preceding five years. The disease was of a mild type.

Phthisis.—6,516 deaths were reported as due to phthisis, being 1,683 less than in the previous year. Other diseases of the respiratory system amount to 7,804 deaths under the heading of bronchitis, pneumonia, pleurisy, &c.

There were 3,161 deaths amongst males and 3,355 amongst females due to phthisis. The most fatal periods of life amongst males and females were between the ages of 30 to 34. The female death-rate was nearly double that of male. Leaving out Negro-Africans, which is a small and fluctuating community, the mortality from this disease was high amongst Jains, even higher than the last year, but this is due to the fact that the Jain population, by the census of 1901, has decreased from 25,225 to 14,248. There is a decrease in the number of deaths amongst Mussulmans, the rate being 13·89 against 17·78 in the last year. Fort North shows a death-rate higher than all the other sections

Infant Mortality.—The number of children under one year of age dying during the year was 7,768, being 5,724 less than in the previous year. According to the census population of 1901, the number of children under one year of age is 9,930, whereas according to the census of 1891 it was 25,291. If these figures remain good, then the mortality of children under one year of age, calculated on that basis, would be 782·27 per 1,000 of infants under one year of age. The number of births registered during the year was 13,520, giving an infant mortality of 574·5 per 1,000 of the births.

The system of registration of births was not satisfactory. Hitherto the system adopted was by employing birth Karkoons to visit houses in different sections and to inquire into the births. This system naturally failed to obtain accurate results. I published the section of the Act and also had it circulated throughout the city explaining that all parents or persons in charge are so liable to give information of any birth subject to a penalty. The new ten dispensaries are registration offices, and notice to that effect

has been well published. More information has already been gained, and when the people become familiar with the system we shall be in a position to ascertain all births occurring in the city. It may be necessary to bring the section of the Act into force and prosecute parents who do not register the births.

General.—From diseases of the digestive system 4,872 deaths were registered, being 5,632 less than in the previous year, and 815 less than the average. Diarrhœa, dysentery and other diseases of the digestive system show a great decrease both against last year and on the average. To diseases of the nervous system 2,971 deaths were registered, being 1,357 less than the last year, but 105 more than the average. 7,804 deaths were ascribed to diseases of the respiratory system, being 4,718 less than in the last year, and 753 less than the average. To diseases of the circulatory system 297 deaths were registered, being 51 less than in the last year, and 5 less than the average.

APPENDIX.

No. 1.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner with the Government of India for 1901.

The mean temperature of 1901 was higher, and the mean rainfall nearly four inches less, than usual. The year was, on the whole, healthier than its predecessor.

2. The average strength of the European Army of India, 60,838, was almost the same as in the previous year, exceeding it by only 285. As usual, the chief causes of admission into hospital were *ague* and *venereal diseases*. The admission-rate of 27, per thousand of strength, from ague was exactly the same as that recorded for the previous year; whilst the admission-rate from venereal diseases fell from 26 to 25. The chief causes of death were, as usual, *enteric fever* and *hepatic abscess*, the former accounting for 27 per cent. and the latter 11 per cent. of all the deaths. The percentage of deaths due to enteric fever, which had been 40 in 1899, fell to 33 in the following year, and has now in the year under report, fallen to 27. The percentage of deaths attributed to hepatic abscess shows little variation: it is the same as that recorded in the preceding year, and somewhat higher than in 1899, when it was 10 per cent. As a cause of invaliding, *secondary syphilis* has ceased to take the first place and is now replaced therein by ague; but the three chief causes of invaliding were, as in the previous year, *ague*, *secondary syphilis*, and *debility*. Between them, these three were accountable for 1,062 invalidings out of a total for the year of 2,393. It is only under the head of invaliding that the returns compare unfavourably with those of 1900. The average strength of the European Army remaining practically the same in both years, the numbers invalided rose from 2,026 in 1900 to 2,393 in the year under report. Under the other heads the returns yield very favourable results. Quoting from the Army Medical Department Report: "The health of the troops was exceptionally good; the admission ratio was lower than that for any of the preceding twenty years, and not since 1883 have the death and constantly sick rates been less."

3. Estimates of the comparative healthiness of the different districts and stations, based on returns of sickness and mortality amongst troops frequently changing from one part of the country to another, are liable to be misleading. As remarked in a previous Memorandum, the special conditions affecting the troops garrisoning the several stations cannot be left out of count. If judged by its returns of sickness alone, a station with a garrison composed largely of young soldiers recently arrived in the country, or of soldiers whose health had suffered from exposure on field service or in camp during epidemics, might acquire a reputation for unhealthiness which it did not deserve. An example may be given in illustration of this from the medical history of the year under report: "Dagshai, which showed a remarkable decrease in 1900 after extensive sanitary improvements and the introduction of a piped water supply in 1899, had an admission ratio of 1103·1 per thousand, an increase of 516·6 compared with 1900 and 44·6 above the decennial average. This increase was largely due to malarial fevers amongst the men of the Essex Regiment, who had just returned from a tour of service in Burma; diseases of the digestive system, skin affections and local injuries were also prevalent, and there were 11 cases of enteric fever with five deaths, compared with six cases and two deaths in 1900 and 19 cases and three deaths in 1899." Judged by its statistics of sickness and mortality, taken by themselves and without explanation, Dugshai would thus be made to appear to have relapsed into a more unhealthy condition than before it underwent the extensive sanitary improvements, and was provided with the piped water supply, mentioned in the report.

4. There was a marked increase in the number of admissions from *influenza* during the year; but this increase was not accompanied by a corresponding increase in the mortality due to it. In the previous year the admissions due to this disease numbered 237 with one death; and during the year under report, 539 with, likewise, only one death.

5. Accompanying the disease of *cholera* mortality amongst the general population by more than 67 per cent., as compared with that recorded in the previous year, the number of deaths from this disease in the European Army of India fell from 88 in 1900 to only 12 in the year under report. The correspondence between the rise and fall of cholera prevalent amongst the native population and its rise and fall amongst the European troops stationed in the midst of that population, is only what might be expected. In last year's Memorandum it was noted that during the years 1898 and 1899, when cholera was in remarkable abeyance throughout India, the mortality due to it in the European Army underwent a corresponding decrease. In the former of these two years only 14 deaths were caused by cholera amongst the European troops, and in the latter only a single death. When, in the following year 1900, cholera again broke out amongst the general population with unprecedented violence, the deaths caused by it amongst European soldiers rose from a single death in 1899, to 88; and now again, with the abatement of the epidemic of 1900, the number of deaths of European soldiers due to cholera falls in the year under report to 12. Since, therefore, the prevalence of cholera amongst the European troops in India is seen to be intimately connected with its prevalence amongst

the people of the country, it would appear to follow that no sanitary measures devised for the prevention of the disease amongst the troops can be regarded as likely to prove completely successful, which are not at the same time calculated to prevent, or lessen, its prevalence amongst the native population. The tendency of further research into the etiology of cholera would seem to unsettle rather than to confirm the belief that the comma bacillus is the one and undoubted exciting cause of the disease. Assuming that cholera is "solely a water-borne" disease, one of the chief difficulties, according to the Sanitary Commissioner, with regard to suspected water examined, is the rarity of finding the true microbe, and the frequency of finding microbes like it. With regard to these latter cholera-like microbes, doubts are entertained as to whether they are dangerous, and whether they may not be a stage in the existence of the true comma. In some of our Memoranda we have expressed doubts as to the utility of treating wells with permanganate of potassium during cholera outbreaks, and have more than once suggested that the question should be made the subject of exact scientific investigation with the object of settling it definitely. In the report of the Sanitary Commissioner with the Government of India we find the subject dealt with as follows :—"The use of potassium permanganate for the disinfection of wells has, as usual, been frequently resorted to during the year; but though opinion on the whole is favourable, there is no proof of its efficacy; and it may be mentioned that recent experiments tend to throw discredit on present means of water purification."

6. Although the number of admissions from *small-pox* decreased from 36 in the previous year to 20 in the year under report, the number of deaths, three, remained the same in both years. At Jubbulpore there were three admissions from small-pox and two deaths; and regarding the three cases it is stated in the Army Medical Department Report that "all bore satisfactory marks of vaccination, and one of the fatal cases had been re-vaccinated in four places only a few weeks before, he contracted the disease." All of the three men were non-commissioned officers, whose duties brought them into daily contact with the native population, amongst which small-pox was prevailing. All of the other 17 men attacked, including the man who died, are said to have borne vaccination marks. It would, however, appear that, in the case of at least one of those 17, the marks were not satisfactory, for we read :—"A confluent form of the disease occurred at Rangoon in the person of a man who had not been vaccinated for 11 years and had not satisfactory marks of protection." If the three cases which occurred at Jubbulpore and of which two proved fatal, were as fully protected by vaccination as the description given of them would seem to imply, they must be regarded as instances, fortunately exceedingly rare, of the impotence of vaccination to protect against attack and death from small-pox.

7. It might have been expected that, accompanying a drier year, there would have been a marked reduction in the sickness from *malarial fevers*. The admissions from intermittent fever show, however, only a decrease of from 18,679 in the preceding year to 17,836 in the year under review. But, judging from the resulting mortality, the attacks would appear to have been less severe; for whilst 40 deaths were recorded under the head of intermittent fever in 1900, the number fell to 22 in 1901. The continued high rate of admissions during the year under report is stated to have been "owing to the fact that most of the hill stations had many more admissions than usual, due to the men sent up for change from the plains being already saturated with malaria, so that it required only chill and damp as exciting causes to light up the fever." It is perhaps yet too soon to expect any substantial decrease in the prevalence of malarial fevers amongst the troops as a result of the active measures being taken for the destruction of infection-bearing mosquitos. The final test of the success, or failure, of these measures will be their effect on the prevalence of malarial fever, and this the records kept of the disease should accurately determine.

8. *Enteric fever* continues to be the disease which occupies the place of chief interest in these annual reports. Whilst the health history of the European Army of India for the year is disposed of in 31 pages, no fewer than 18 of these are devoted to an account of enteric fever. It is gratifying to find that the decrease in the severity of the disease in the European Army of India, which was so marked a feature of the medical history of the previous year, still continues. Going no farther back than 1898, when the death-rate recorded from enteric fever was 10·17 per thousand of strength, we find that this fell in the following year to 5·14, and in 1900 to 4·77. The decrease has continued during the year under review, which returns an enteric fever death-rate of only 3·32. With the cessation of the lessened influx of drafts from England, one of the chief causes to which during the last two years the remarkable decrease in the fatality of enteric fever was generally ascribed, it remains to be seen if the disease will tend to regain its former prevalence. The Sanitary Commissioner supplies, as usual, an excellent *résumé* of the latest additions to the literature of enteric fever. Confidence in some of the cherished theories and beliefs hitherto entertained regarding the causation of the disease would seem likely to be disturbed by recent investigations. It has been found more difficult than ever to recover the specific microbe from suspected water, the progress of knowledge having led investigators to be less easily satisfied in the matter of identification. In fact, Sims Woodhead, agreeing with others as to the difficulty of finding the bacillus in water, states that he has never succeeded in isolating it therefrom, "except when he had previously placed it there himself." Yet, it is believed to be usual in India to forward samples of water for examination, and to expect the bacteriologist to state definitely whether the specific bacillus exists, or does not exist, therein. Quoting from the Report on the Progress of Hygiene for 1901-02, by Major Firth, Professor of Military Hygiene in the Medical Staff College, London :—"As regards the risks attending overcrowding in tents, and the evils resulting from food pollution by means of dust and flies, a most valuable mass of evidence has been published by the United States Government in the form of an Abstract of Report on the Typhoid Fever Epidemics in the Volunteer Camps of the United States Army in 1898. Many of the conclusions formed by the Commission who drew up the report are of great suggestiveness and importance. They found that in the majority of cases, infected water was not an important factor in the spread of the enteric fever, but that there was much to indicate the necessity of extraordinary measures for the prevention of direct infection from man to man, and of infection through soil and from the clothing, bedding, and tentage of the

troops." Among other questions that have recently been asked, is the one as to whether enteric fever can be caused only by the bacillus of Eberth, or whether infection by other bacilli may not give rise to fevers indistinguishable from it both chemically and pathologically. But the Report of the Sanitary Commissioner with the Government of India, and that of Professor Firth above referred to, will have to be consulted by those who wish for fuller information regarding recent research into the "nature or entity of enteric fever and its etiology."

9. For the year under report a further decrease in the prevalence of *venereal diseases* in the European Army of India has to be recorded. Ever since the year 1895, when the admission-rate attained the enormous ratio of 522·3, per thousand of strength, there has been a continual decrease year by year until now, in 1901, the ratio has fallen to 276·0. During the preceding year it was 298·1. The lessened influx of drafts of young soldiers from England during the last two years may have contributed to diminished prevalence of these diseases, as it has undoubtedly done to diminished prevalence of enteric fever. Now that the annual despatch of drafts of young soldiers from England to India has been resumed, it is possible that the returns may in future show a check in the steady decrease from year to year in the number of men suffering from these complaints. But apart from whatever influence age, and length of residence in the country may have in strengthening the soldier's self-control and enabling him more fully to realize the disastrous consequences likely to follow his giving way to temptation, it is evident that strenuous efforts are being made, especially by the medical and regimental officers, as well as by chaplains, to safeguard the men under their charge from the dangers to which they are so constantly exposed in most Indian stations. "Lectures and warnings were frequently addressed by medical officers, chaplains, and regimental officers; means of ablution were provided and their use encouraged; measures were taken to prevent the women being in evidence or soliciting the men; dangerous places were placed out of bounds; concerts and other evening amusements were provided."

10. The strength of the *Native Army*, 122,806, remained nearly the same as during the preceding year, when it was greater by only 657. There was a marked decrease in the death-rate from 14·04, per thousand of strength, to 10·68, or to slightly below that recorded for 1899. This decrease was due to lessened mortality from nearly all the chief diseases, but especially from *cholera*. From this last disease 388 deaths were recorded in the preceding year, and only 19 during the year under report. The decrease in the cholera mortality was synchronous with its decrease amongst the general population. Some attempt is made to account for the outbreaks of cholera in the case of four of the regiments attacked. In one of these regiments unsound fruit is said to have caused the outbreak; and it is added that as soon as fruit was forbidden no more cases occurred. "As to the other regiments affected, the only point mentioned, when anything is said at all, is the presence of the disease in the neighbourhood." From the nature of these statements it may be inferred that the observations of another year have done little to dispel the obscurity in which the origin of cholera outbreaks is still usually found to be involved.

11. In spite of the admissions from *influenza* having risen from 114 in the previous year to 1,232 in the year under report, the number of deaths caused by it was only three, as compared with four in the former year. The type of disease would thus appear to have been mild. As usual, *ague* was the chief cause of sickness in the Native Army: it was accountable for upwards of 43 per cent. of all the admissions into hoposital, and for a total of 120 deaths. But *remittent fever*, although the cause of a percentage of only 1·72 admissions, was yet accountable for 154 deaths. This year, again, *pneumonia* takes the first place as a cause of mortality in the Native Army, although the number of deaths due to it decreased to 334 from 410 in the previous year. "The admission-rate from *enteric fever* was only half as high as in the preceding year, and the death-rate was also diminished. The ratios for native troops and prisoners are very unlike those for European troops. The statistics do not yet reflect the opinion, so prominent of late, that enteric fever is quite common among natives; and so long as medical officers return few cases, the statistical tables cannot show many. As a matter of fact, in spite of the way in which the attention of the medical officers has been called to the possibilities, the number of cases and the ratio were lower than in seven out of the ten years preceding and below the averages." The opinion that enteric fever is more prevalent among natives of India than has hitherto been supposed, appears to have gained adherents by frequent repetition. An attempt has been made to explain the comparative immunity of adult natives, such as those who are found in the ranks of the Native Army, and those who constitute the bulk of the prisoners in Indian jails, by the hypothesis that natives have mostly had enteric fever when children, and have thus been rendered insusceptible of further attack. Apart from the absence of any reliable record of facts which would support such a hypothesis, Brault concludes, from testings of the blood of Arab children, that "no support is lent to the view that adult immunity depends upon a prevalence of the disease in childhood." Whilst *tubercle of the lungs*, *plague*, *and cerebro-spinal fever* were all more prevalent and fatal in the year under report than in the previons year, the mortality from *dysentery* and *diarrhœa*, greatly diminished. The number of deaths from the last mentioned two diseases was 58 as compared with 114 in 1900.

12. The ratio of admissions from *veneral diseases* in the Native Army, which had increased to 42·5 per thousand of strength in the preceeding year, again fell to 34·3, or to almost exactly the same as that recorded in 1899. The increase in 1900 was ascribed, in some parts of India, to the number of destitute women who, under pressure of famine, resorted to prostitution. The reversion of the sick-rate from these diseases to normal, on the disappearance of famine, would seem to lend support to this explanation.

13. Accompanying the disappearance of famine from most parts of the country, and the return of more prosperous times, there was a marked decrease in strength of the *Jail* population of India from an average of 121,812 in the previous year to 117,203 during the year under report. The health of the prisoners, like that of the general population, improved; and although the admission-rate was nearly the same in both years, the death-rate decreased to 26·5 from 34·2 in 1900. As usual, *bowel*

complaints, pneumonia and *tubercle of the lungs* were the chief causes of death. Between them, dysentery and diarrhœa were accountable for 26·8 per cent., and pneumonia and tubercle of the lungs together, for 27·8 per cent. of the total jail mortality. The remark made by the Sanitary Commissioner with the Government of India in his Report for 1900, still holds good for the year under report. "The heads of jail mortality requiring special attention are bowel complaints, tubercle of the lungs and respiratory diseases." As was only to be expected, the abatement of the destructive epidemic of *cholera* which prevailed amongst the general population of India during the preceding year was accompanied by a fall in the death-rate from that disease in jails. This rate which had been 2·23 in 1900, fell to ·90 in the year under report. It might be supposed that in a jail, if anywhere, it would be possible to ascertain the precise means by which the inmates became infected by cholera; but, as a matter of fact, the experience recorded in the case of the three central and five district jails attacked by cholera in the Madras Presidency during the year, is the ordinary one. "The exact manner of introduction into jails was not traced in any case, though flies, rise of subsoil water,and disturbance of cholera-burial-ground soil are mentioned in connection with causation." There is, however, an exception to this common experience reported from Burma. "An epidemic of 20 cases of cholera with 12 deaths in the Insein Central Prison was referred to infected tobacco introduced by a prisoner sent in from a police lock-up without any intimation that he had for some time been in contact with cholera cases." It is not stated if the *comma baccillus* was discovered in this case.

14. From *enteric fever* there were 41 admissions, with 20 deaths, recorded during the year. The conditions existing in jails are such as might be expected to afford facilities for accurate observation of cases from their inception to their termination in recovery or death. In the latter event, the correctness of the diagnosis could, probably in all cases, be checked by a *post mortem* examination. The death-rate recorded from enteric fever, per thousand of average strength, was ·17 amongst prisoners in jail, ·12 in the Native Army, and 3·32 in the European Army of India.

15. There was a serious increase in the prevalence of *cerebro-spinal fever* in the jails of India during the year; the number of deaths increasing from 79 in the previous year to 102. Taking into account the widespread prevalence of *plague* amongst the general population, 36 deaths from the disease in a jail population of greatly more than a hundred thousand, cannot be considered excessive.

14th October, 1903.

No. 2.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bengal for 1901.

As measured by its record of vital statistics, the year 1901 was not so unhealthy as its predecessor. Whilst the birth-rate was higher, the death-rate was lower than in 1900. Yet, although less than in the previous year, the death-rate was somewhat in excess of the average of the last five years. The rainfall was generally in defect and unevenly distributed. "The late commencement of the monsoon and its early cessation affected the agricultural out-turn, which was lower in almost all the districts." Such conditions would unfavourably influence the public health; and, as remarked in the Government review of the report, are to some extent reflected in the vital statistics of the year. Those who maintain that an increasing population is conclusive proof of increasing prosperity should be satisfied that the prosperity of the province of Bengal has undergone no diminution during the past ten years. Notwithstanding the destructive effects of famine, cholera, and plague, the population numbers of the year under report exceed those of 1891 by not far short of three and a half millions.

2. The *birth-rate* recorded for 1901 was 38·57 per thousand of population. But for the great unhealthiness of the preceding year and the high prices of food grains which prevailed in many districts during that year, it would doubtless have been much higher. In 1899, a birth-rate of 42·96 was recorded. These figures may be taken as an indication of the very great improvement in the registration of vital statistics which has been effected in this province within the past ten years. Prior to 1892 the registration of births in Bengal was limited to municipalities; but was in that year extended to the same area as the registration of deaths. The ratio of births recorded for 1892 was only 28·1 per thousand of population for the province as a whole. Even now, complete accuracy cannot be claimed for the registration of births; but, as the result of the inquiries made by the vaccination staff in towns and villages regarding upwards of half a million of births and deaths, it was ascertained that only a percentage of 1·2 of the former and ·98 of the latter had not been recorded.

3. The fall in the *death-rate* below that for the preceding year was chiefly due to the abatement of the epidemic of cholera which prevailed with unprecedented severity during 1900. The provincial death-rate for the year under report was 31·04 as compared with 34·98 in 1900; cholera accounting for only 1·48 of the former rate against 4·64 of the latter. "As usual," writes the Sanitary Commissioner, "the mortality from cholera, dysentery, and diarrhœa and other causes was much larger in towns than in rural areas, while fever continued to prevail with greater severity in rural areas." Such would be the conclusion to which the statistics of mortality would lead; but, as

suggested in previous *Memoranda*, it appears probable that in towns the diagnosis of disease is somewhat more intelligently effected than in rural areas, with the result that a proportion of the deaths lumped together under the head of "fever" in rural circles is distributed in town circles under the heads of the several diseases to which they were really due. In the Government review of the report a similar explanation is suggested of the record of a greater number of deaths from dysentery and diarrhœa in towns than in the country.

4. *Chief Diseases.—Cholera*, which was in marked abeyance in Bengal, as in the rest of the Indian Empire, during 1898, increased in prevalence in the following year, and culminated during 1900 in the most destructive epidemic on record. During the year under report it again subsided within its ordinary limits, accounting for only 110,753 deaths as compared with 345,878 in the previous year. The cause, or causes, of these fluctuations are still far from being clearly understood. If, in accordance with general belief, cholera infection is "water-borne," an examination of the water-supply might be expected to yield some explanation of the fact that, whilst in 1898 only 65,020 people died of the disease in Bengal, this number was five times greater in 1900, and fell again in the year under report to 110,753. The Sanitary Commissioner deals with the question of the influence of the water-supply on cholera mortality at some length. "The severe prevalence of the disease throughout Orissa," he says, "appears to have been due to the short rainfall during 1901, which led to serious pollution of the drinking water-supply." It is presumed that by pollution is meant infection with the specific cholera poison, although it is not stated how this arose. The deficient rainfall is, on the other hand, supposed to have had ultimately an opposite effect in some parts of the province. The explanation is ingenious, and not inconsistent with that already quoted. "The deficient rainfall of the previous year left most of the tanks only partially replenished, and the early cessation of the rains compelled the people in many instances to use the water up to save their withering crops. Thus, the close of the year 1900 saw most of their tanks all but dry, and the scanty rainfall during the early months of this year led to their being quickly dried up, or rendered wholly useless as a source of water-supply. The people were thus prevented from obtaining their water-supply from these filthy tanks and ditches, and in this respect the scanty rainfall during the earlier months of 1901 seems to have been a blessing in disguise." In many districts disinfection of wells by permanganate of potash was carried out with what are said to have been "good results." In some places the people were eager to disinfect suspected wells, whilst in many others the measure was strongly objected to. Hitherto, the disinfection of wells with permanganate of potash has not been conducted with the scientific precision necessary to arrive at a decisive conclusion regarding its value. Most frequently, hospital assistants, vaccinators, and other persons untrained in scientific methods and unaccustomed to the exact observation and record of facts, have been those chiefly entrusted with carrying out the disinfection of the water supplies; and it is mostly on the evidence of such agents that the estimate of the usefulness of the permanganate as a disinfectant of water contaminated with the cholera poison is based. Perhaps nowhere could an experiment to test the value of the permanganate as a disinfectant of drinking water be carried out under conditions less liable to error than in a prison. In the month of August of the year under report, a severe epidemic of cholera commenced in the Central Prison at Lucknow, and caused 27 deaths. Regarding this outbreak, Major Mactaggart, Inspector-General of Prisons, writes:—"As I have mentioned when dealing with the health of the Lucknow Central Prison, there was nothing to show how the disease was introduced into this jail, but as cholera was severely epidemic in Lucknow City and in the villages surrounding the jail, it is not surprising that the jail was ultimately affected, either through the medium of flies, or in some other ways which we have been unable to trace. The wells in the jail were constantly treated before and during the outbreak with permanganate of potash, and after the first two or three cases the drinking water of the prisoners was boiled; but neither permanganating the wells as carefully as it could be done, nor boiling the water, had apparently the smallest effect on the epidemic. The move into camp appeared to lessen the number of cases, but it was not immediately successful in checking the disease." It will be allowed that the facts thus carefully observed and recorded, under circumstances to exclude error, carry more weight than the reports and opinions of the class of persons ordinarily deputed to disinfect wells during cholera epidemics. This year, again, the inoculation of emigrant coolies against cholera seems to have yielded satisfactory results. "From a summary it appears that, out of 275 uninoculated coolies, 21, or 8·36 per cent., got cholera, 10 of the cases ending fatally; while out of 414 inoculated coolies, only five, or 1·2 per cent., got the disease, but none died from it." If these figures may be accepted as the normal measure of protection conferred by anti-cholera inoculation, it would obviously be in the interests of the coolies and of those concerned with their conveyance from the place of their recruitment to their destination in Assam, that all of them should, before commencing their journey, undergo inoculation.

5. The most severe epidemic of small-pox which has visited the province within the period for which reliable statistics are available, carried off 37,680 persons during 1901. In the district in which it proved most destructive to life the disease is said to have been spread by small-pox inoculation. Since it has been established beyond question that vaccination is as effectual a protection against small-pox as inocculation, and since vaccination is without danger either to the individual upon whom it is practised or to those about him, whilst inoculation is, on the contrary, not only full of risk to the life of the person inoculated, but is a source of danger to his neighbours; the suppression of the latter method of conferring protection against small-pox, so soon as vaccination is placed within the reach of all, would appear to be unattended with either injustice or hardship to anyone. The only sufferers would be the inoculators, whose means of livelihood would be interfered with; and even these might be deprived of a grievance by being entertained as vaccinators. The suppression of inoculation would however exercise but a very limited effect on the prevalence of small-pox in a densely peopled country from some parts of which small-pox disease is probably never entirely absent. The only effectual means of putting an end to destructive small-pox epidemics are the general and efficient protection of the inhabitants by vaccination and revaccination. There was a large increase of the numbers vaccinated during the year. Such increase nearly always takes place during, and as the consequence of, the prevalence of small-pox in epidemic form. But it

is only necessary to place the number of children of less than one year of age who were successfully vaccinated beside the number of the same age available for vaccination, to realise the extent to which vaccination falls short of fully protecting the infant population of the province against small-pox. During the 12 months of the calendar year 2,870,806 births were registered, and 519,630 deaths of children under one year of age, leaving 2,351,176 available for vaccination; whilst during the 12 months of the vaccination year, 733,253 children under one year of age were successfully vaccinated. Small as the latter number may appear as compared with the number of children born, it exceeds the previous year's number by no less than 143,877, and is indicative of decided progress. The work of the Department has been seriously hindered by the constant deputation of members of the vaccination staff for employment on plague duty, or other special work.

6. *Plague* increased rapidly during the year, the deaths due to it rising from 30,134 in the previous year to 70,746, exclusive of those which took place in Calcutta. The Sanitary Commissioner strongly advocates inoculation as an efficient preventive measure against the spread of the disease. It is not claimed for inoculation that it is an absolute protection against plague, a certain proportion of the inoculated subsequently contracting the disease; but even were it as complete a protection against plague as vaccination is against small-pox, it may be questioned if it would be feasible to provide the amount of serum required for the inoculation of more than a fraction of a population so enormous as that of Bengal. The staff of trained medical officers required to carry on the work of inoculation would also be very large; and even were a sufficient quantity of serum procurable, as well as a sufficient staff of medical officers to apply it, there would still remain the uncertain temper of the people to be reckoned with. Fortunately "the people in rural areas now understand the value of "evacuation of infected houses, and readily resort to it." On the appearance of plague in a Himalayan district, the inhabitants have been accustomed from time immemorial to evacuate their villages as the readiest and most effectual means of bringing the outbreak to an end. When thoroughly carried out, evacuation of infected villages would seem to be no less effectual in cutting short an outbreak of plague in the plains than it has been found to be in the hills.

7. *Fevers* were, as usual, credited with having been the cause of more deaths than all other diseases together. Nearly 70 per cent. of the total number of deaths for the year were registered under this head. The inclusion of many deaths due to plague under the head of "fever" is believed to have had a share in swelling the return of deaths attributed to the latter. Much that is obscure regarding the nature of the fevers and the causes which determine the severity of their incidence in the different parts of the province still awaits investigation. It is essential, however, when competent officers can be deputed to carry out scientific work of this description, that they should be allowed sufficient time for its completion. Regarding the employment of the officers placed at his disposal, the Sanitary Commissioner writes: "Those I have had for short periods could do no valuable work for "the reason that before they realised the nature of the work they were transferred, while those who "were employed for longer periods in northern Bengal and western Bengal circles, have since 1897 "been employed entirely on plague work to the detriment of ordinary sanitation." It would be unreasonable to expect that scientific inquiries could be conducted to a satisfactory conclusion under such conditions.

8. A Report from the Sanitary Board follows that of the Sanitary Commissioner. Only one meeting of the Board was held during the year. A number of estimates for sanitary works were prepared and others were considered by the Board; but if the extent of the sanitary works actually carried out during the year, may be judged of by the amount expended in their execution, it would not appear that they can have been on a scale of great magnitude. "The total cost of sanitary "works carried out or in progress in towns and rural areas, by Municipalities, District Boards, "Government, and private individuals during 1900-1901" did not greatly exceed five lakhs of rupees in the case of towns, and six lakhs in the case of rural areas. Relatively to the sanitary needs of a province with a population numbering upwards of seventy-four millions these sums seem inconsiderable.

No. 3.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the United Provinces of Agra and Oudh for the year 1901.

In the history of the public health for the year there was little of an unusual character, or such as to call for lengthened comment. The annual report, written by Major Chaytor-White, who laboured under the disadvantage of having held charge of the duties of Sanitary Commissioner during no part of the year dealt with, is clear and concise. The year was a healthy one. Its chief meteorological features are described in considerable detail. Of these the most remarkable were the excessive heat of June and the defect in the rainfall of that month.

2. Throughout the report the census population numbers of 1901 are used in the calculations of ratios. The census just taken affords another illustration of the insecurity of the basis on which

estimates of population during intercensal years rest. If the population of these provinces for the year 1901 is estimated by adding to the figures of the previous census the excess of births over deaths during the intervening years, the total will be found to be in excess of the actual number by more than a million and a half. When a similar estimate was made at the end of the ten years following the taking of the census of 1881, the difference between the estimated and the actual numbers was only 206,436; and the smallness of this difference was accepted as an indication of the comparative accuracy with which the registration of births and deaths had been effected during those ten years. The divergence has thus increased more than sevenfold during the ten years just ended; but in view of the continued and even increased attention given to registration, it is difficult to believe that this can be due to a falling-off in the accuracy with which births and deaths were recorded. The explanation of this wide divergence between the estimated and the census population numbers of 1901 the Sanitary Commissioner confesses to be far from simple. He thinks "it is probable that deaths occurring among people on famine works were not fully reported; especially when cholera broke out in epidemic form." But it seems scarcely credible that a million and a half of deaths would escape registration even under such conditions of famine and epidemic disease. Calculated in the ordinary way for the years intervening between 1891 and 1901, by assuming that it would increase during those ten years at the same rate as that at which it had increased during the preceding ten years, the estimated would have diverged even more widely from the actual population numbers; for, whilst the census of 1891 showed an increase of more than two millions and three quarters over the preceding census numbers, the census of 1901 showed an increase of little more than three-quarters of a million over the figures for 1891. In exact figures, the population of 1901, estimated by adding excess of births over deaths to the preceding census numbers, differed from the population ascertained by enumeration by 1,595,229; and as estimated by assuming the rate of increase to have been the same as during the preceding ten years, it differed from the actual numbers by 1,967,293. Consequently, as the actual difference between the census numbers of 1901 and those of 1891 was only 786,991, it is obvious that the employment of estimated population numbers for the years intervening between the taking of the census of 1891, and that of 1901 would have increased, and not diminished, the error arising from using the previous census figures in calculating ratios. The disturbing effects of famines and epidemics cannot always be excluded from the reckoning when the population of an Indian province is being estimated.

3. The *birth* and *death* rates recorded for the year bear testimony to its healthiness. The former was above, and the latter below the quinquennial mean. The mortality ratios from all the chief diseases were less than the mean ratios for the decennium 1891–1900. The number of deaths from small-pox was the lowest on record, and yielded a death-rate of only 0·02 per thousand of population. Commenting on these figures, the Sanitary Commissioner says;—"The beneficent effects of vaccination were assuredly never more eloquently proved, and in this respect, we can, I venture to think, compare favourably with many European communities." The reduction of the mortality from small-pox to less than a thousand deaths per annum, in a population exceeding forty-seven millions, would seem to justify such a testimony to the efficiency of the vaccination department of the Province; but it needs no prophet to predict that the series of years of small-pox quiescence following the great epidemic of 1897 will inevitably lead up to another, although probably less violent, epidemic. An examination of the diagram in the vaccination report shows that, in a large number of districts, the ratio of successful primary vaccinations did not reach to more than half the birth rate. This was especially the case in the province of Oudh. It follows, that a large residuum of unprotected persons must be accumulating year by year in these districts. This accumulation will continue until the recurrence of a season favourable to the spread of small-pox, which is never altogether absent from the province, when another epidemic will break out, carrying off a certain proportion of the unprotected and rendering immune from further attack those who recover. Regarded in this light, the remarkable freedom from small-pox which the province has enjoyed since the fatal epidemic of 1897 carried off no fewer than 87,127 persons, is seen to favor the accumulation of the unprotected and susceptible element in the population.

4. Under the head of *fever* were recorded, as usual, by far the greater number of deaths during the year. To this cause was attributed a ratio of 23·46 of a total of 30·30 deaths from all causes. A very useful return of deaths according to their causes, verified by medical officers, medical subordinates and private medical practitioners, is annually included in the sanitary report of these provinces. As in previous years, a comparison between this and the general provincial returns shows that, in the latter, the mortality attributed to fever is enormously exaggerated, whilst that due to bowel complaints is greatly understated. Out of the total number of 11,578 deaths verified by professional agencies, it is worthy of remark that 17 were diagnosed to have been due to enteric fever. Of the 5,303 deaths amongst children under 16 years of age not one is stated to have resulted from enteric fever. In the course of his remarks on malarial fevers and the measures found to be most effectual in diminishing their prevalence, the Sanitary Commissioner says:—"I am inclined to think that money will be better spent in improving surface drainage and filling in tanks and depressions than in organising the so-called mosquito brigades, a measure that can only have a temporary benefit on a community. Considering the amazing fertility of the female *anopheles*, a continuous war would have to be waged to produce even an appreciable effect." In the prevention and cure of malarial fevers, drainage and quinine have gained rather than lost in importance as the result of recent research and discovery.

5. Deaths from *plague* are not separately recorded in the returns; but the disease seems at length to have secured a firm foothold in the province, and, in the words of the report, continues to recur annually in an ever-widening sphere. "Bad drainage, encroachment on streets, shutting out sunlight, overcrowding of inhabited sites in cities, and the prevention of through ventilation—all tend to render eradication of the disease more difficult and the spread of it more certain."

25th May 1903.

No. 4.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Punjab for 1901.

The area of the province has undergone material reduction since the last Report was written. Five of the districts hitherto constituting part of the Punjab are now included in the new North-Western Frontier Province; whilst the name of one new district appears in the list of the 27 still belonging to it. Notwithstanding the detachment of so many districts, the population, owing to its "natural increase," falls not far short of the number recorded when the census of 1891 was taken: it was then 20,724,940 and is now 20,274,136. "In the present report the comparisons which are made between the figures for 1900 and those for 1901 are comparisons of births and deaths registered in the area, and calculated on the population of the Punjab as at present constituted." It might have been useful if some explanation had been attempted of the causes which led to the increase in the population numbers in some districts and their decrease in others during the interval between the taking of the census of 1891 and that of 1901. Whilst in several districts the population numbers show a decrease, which is, however, in no case very considerable, in the majority of them the numbers show an increase. In one district the population has more than doubled between 1891 and 1901.

2. Judged by its vital statistics, the year under report was not a healthy one, although far less unhealthy than its predecessor. The *birth-rate* was 3·4 and the *death-rate* 11·6 lower than these rates for 1900. In the calculation of the ratios of births and deaths for the year, the new census figures of 1901 are used for the year under report, whereas the census figures of 1891 were, of course, used in calculating those ratios for 1900. But the population of the province had largely increased in the interval between the taking of the census of 1891 and that of 1901; so that the use of the census figures of the latter year has the effect of lowering the recorded birth and death ratios for the year under report. Had the same population numbers been used in calculating the ratios for both years, the birth-rate for 1901 would have compared more favourably and the death-rate less favourably with the birth and death-rates for 1900. The Sanitary Commissioner writes: "It will be seen that in 1901, according to the registered mortality, next to Bombay, the Punjab was the unhealthiest, and Madras, with a remarkably low death-rate of 21·3, the healthiest province in India." But vital statistics are still too imperfect in some provinces to admit of safe deductions being drawn from them. As a matter of fact, the public health during the year was far from good in the Madras Presidency. A recorded death-rate of 36·1 per mille of population in the Punjab, and a recorded death-rate of 21·3 in Madras cannot be accepted as a reliable measure of the relative unhealthiness of these two provinces during the year; they should rather perhaps be taken as an approximate measure of the comparative efficiency with which the registration of vital statistics is carried out in each of them.

3. In the Government review of the Report, the year, as regards its climatic conditions, the price of food, and wages of labour, is described as not having been unfavourable to the public health. *Cholera*, which in 1900 prevailed in destructive epidemic form, was almost entirely absent in 1901. In the former year no fewer than 24,840 deaths were caused by it; and in the latter only 180. A contrast so striking between the mortality from cholera in two consecutive years naturally suggests inquiry into the conditions which in the one year favoured its prevalence, and in the other conduced to its almost complete disappearance. The previous year was one of severe famine; but the history of cholera in other years and provinces shows that the prevalence and severity of this disease may bear no proportion to the extent and severity of the accompanying famine. Medical men are nearly unanimous in declaring cholera to be a "water-borne" disease. Assuming this to be the case, it might have been useful had an endeavour been made to ascertain in what specific respect the water-supply during the cholera year of 1900 differed from the water-supply during the non-cholera year of 1901.

4. *Small-pox* was less prevalent than in the previous year, the death-rate falling to 0·31 per mille of population from 0·51. Since the invasion of the Punjab by plague, *vaccination* has been carried on under great disadvantages. The causes which have led to the continued decrease in the number of persons vaccinated since 1896–97 are summed up in the Government review of the Vaccination Report for 1901–02. "Briefly, they have been a decrease in the number of births, scarcity, malarial fever, mortality among cattle, which has made it difficult to get buffalo calves, return of persons to the Native States who had sought refuge in our famine camps, and the employment of the Deputy Sanitary Commissioners and of vaccinators on plague duty, to which, in the case of the year 1901–02, may be specially added unusual sickness, which rendered a number of children unfit for vaccination, and the continued existence and disastrous spread of plague in the province, and in the principal native states, which caused a suspicion of vaccination operations in certain badly infected tracts, where, the people being in a disturbed frame of mind, it was thought the presence of vaccinators might lead to trouble." A favourable feature of the season's work is, as usual in the Punjab, the high proportion of children under one year of age amongst the vaccinated. The successful operations amongst infants under one year constituted 82 per cent. of all the successful cases. The quality of the vaccine lymph in use was in some cases very unsatisfactory. The need for improving the quality of the vaccine lymph supply is a matter of vital importance. Until the arrangements have been completed for the preparation of preserved lymph of reliable quality it might be advisable to employ, as far as practicable, only lymph direct from the calf. It is above everything essential for the successful working of the vaccination department, composed as it chiefly is, of a large number of subordinates on small salaries, and scattered over the province, that it should be efficiently supervised. The withdrawal of the Deputy Sanitary Commissioner for plague duty cannot but have had a very prejudicial effect on the work of vaccination in the Punjab during recent years. With the appointment, at length, of a whole-time officer to the charge of the Department, it may be expected that the work of the coming year may show improvement both in quantity and quality.

5. Of deaths from *plague* 14,959 were registered. But probably no great reliance can be placed on these figures. The Government point out that, at least, 17,000 deaths were due to plague. During the previous year only 495 deaths were reported as having been caused by it. These figures bear witness to the startling progress which the disease has made during 1901. The Sanitary Commissioner writes :—" In consequence of the abandonment of cordon arrangements in October 1900, but chiefly on account of the relaxation of all compulsory measures some months later, there was an enormous increase in the mortality from plague in 1901." The vast majority of cases were of the bubonic type of plague, though cases of pneumonic and septicæmic type were observed. In so far as information was obtainable, the infection of villages appeared to be due in nearly all cases to human intercourse. " In no instance could proof be obtained that infection was introduced by rats, though in many villages large numbers of dead rats were observed before the disease had spread." In connection with the question of anti-plague inoculation, the Sanitary Commissioner's caution should not be overlooked. When noting that a mild and less fatal form of the disease was reported from certain places in which a large number of the population had been inoculated, Colonel Bamber goes on to say :—" But before drawing conclusions favourable to inoculation, we require to know what the death-rate is in villages which have been affected by the disease for several years where inoculation has not been carried out. We know that other epidemic diseases, when first introduced into a community which has never suffered from such diseases, are much more deadly than they are among communities which constantly suffer from them."

6. To *fevers* was attributed by far the greater proportion of the mortality of the year. Although the death-rate from this cause fell from 32·3 in the previous year to 25·3 per mille of population, it was still much above the average. It is suggested in the Government review of the report that some of the deaths really due to plague may have been registered under the head of fever. This seems also to have been the case in the Province of Bengal; but in the Bombay Presidency it has been observed that, accompanying the rise and fall of plague prevalence, there is a corresponding movement in the mortality rate credited to " other causes " ; whilst fever, being a prominent symptom of plague, there is a tendency to avoid reporting deaths from it lest such report might suggest the existence of plague, and so lead to troublesome inquiries with the object of discovering the existence of plague cases.

7. *Sanitary Works.*—The report of the Sanitary Engineer, who has recently been appointed by the Punjab Government, follows that of the Sanitary Commissioner. The list of important sanitary projects submitted to the Sanitary Engineer is a long one. A water-supply and two drainage schemes were in hand during the year, whilst two more drainage schemes had been sanctioned. The important question of sewage disposal is receiving the attention of the Sanitary Engineer. He writes :—" During the year I took special note of the action taken by Municipal Committees to utilise sewage for irrigation purposes. Several towns are now taking this important matter up keenly, and as the cultivators are beginning to see more clearly what the advantages of farming with sewage are, there is more competition to pay a respectable price for it." Provided the necessory funds are available, there is scarcely any limit to the number of useful sanitary improvements which may now be carried out under expert supervision. " The only discouraging factor that I see ahead," writes the Sanitary Engineer, " is the one of ways and means."

13th May 1903.

No. 5.

Memorandum by the Army Sanitary Commission on the Report on the Sanitary Administration of the North-West Frontier Province, for the year 1901.

This is the first Sanitary Report on the recently created North-West Frontier Province. The five districts, of which the new province consists, previously formed part of the Province of the Punjab. Two of these five not having been transferred in their integrity to the new province, their vital statistics cannot be used for comparison with those recorded for them in the previous years. The total population of the new province, according to the census of 1903, is only a little over two millions, a number in some cases exceeded by the population of a single district in certain of the older provinces of India.

2. The year was a healthy one; the harvests were generally good, and there was no scarcity of food in the province. The recorded death-rate was only 19·2; but beyond indicating in a general way that the mortality was lower than usual, such figures are not worthy of much confidence. Quoting from the Proceedings of the Agent to the Governor General and Chief Commissioner of the Province : —" The registration of the births and deaths does not seem satisfactory." As the result of the inquiries made during the year by the Divisional Inspectors of Vaccination, it is estimated that one birth in six, and one death in ten, escape registration. It is safe to conclude that a considerable proportion of the births of female children remains unregistered, when it is seen that, according to the returns, the ratio of male to female children born is stated to be 123·2 of the former to 100 of the latter, and in one district 138·7 to 100. " This is said to arise from the unwillingness of Pathans to

register the births of female children." The recorded birth-rate of 29·5 for the province is not, however, an exceptionally low one, and exceeds that of several other Indian provinces, such as those of Madras, Bombay, and the Central Provinces, for 1901.

3. Of the chief diseases, *fever* had attributed to it by far the greater part of the mortality of the year. Under the head of *cholera*, 117 deaths were registered, as compared with 3,275 in the previous year, the Peshawar district and city contributing most of the cases. *Small-pox*, although considerably less fatal than in the previous year, accounted for 955 deaths. There was a falling-off in the number of vaccination operations during the year 1901-02 as compared with the numbers recorded in each of the two previous vaccination seasons; but this decrease is more apparent than real, and is largely due to the reduction in the size and population of the Bannu and Dera Ismail Khan districts, consequent upon the abstraction of portions of each of them to form the new district of Mainwali, now included in the Province of the Punjab. It appears, however, from the table given in paragraph 5 of the Vaccination Report, that the number of operations performed by each vaccinator was smaller in 1901–2 than in either of the two preceding years. Animal lymph was chiefly employed, and yielded the high percentage of 99·12 successful cases as compared with 96·75 when human lymph was used, and with only 88·08 when lymph prepared with vasaline was used. Inoculation is practised in the province, and so long as this continues to be the case, small-pox will probably be rarely, if ever, entirely absent from some part of it. If the success of the civil surgeon of Mardan in overcoming the prejudices of the people against vaccination, and inducing them to accept it in preference to inoculation, should be attained in other districts, there seems good reason to hope that the practice of the former may at no distant period entirely supersede that of the latter in the province. So far, *plague* has not extended to this part of India; "no case of plague was reported during the year."

4. No large sanitary works were undertaken during the year; but much was done, by cleaning and repairing wells, to improve the water supply, more especially in the Dera Ismail Khan district.

14th October, 1903.

No. 6.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Burma for 1901.

The weather conditions of the year were favourable to health. Although the rainfall was considerably in excess of the mean, the average humidity was less. The price of rice, the staple food of the province, varied but little from that which prevailed during the preceding year. The number of deaths was less than in 1900, although somewhat greater than the previous five years' average. But in comparing the mortality of the year under report with that of preceding years, the rapid increase of the population of the province has to be kept in view. According to the census of 1901, the population of the same area as that which yielded the census numbers of 1891 had, during the intercensal ten years, increased by 24 per cent. Assuming that the health of the year under report and that of one of the preceding years were equally good, the larger population of the former would naturally yield more deaths than the smaller population of the latter, provided the constitution of the population of both years, with regard to age, sex, &c., were similar. There is a wide divergence between the population numbers obtained by actual enumeration and the population numbers as estimated by adding to the census figures of 1891 the number by which the births exceeded the deaths during the intercensal ten years. According to the former the population has increased by 24 per cent., and according to the latter by only 14 per cent. But, although the defective registration of vital statistics is probably responsible in great part for this divergence, part of it is also doubtless due to the excess of immigrants over emigrants. No *data* are available by means of which a conclusion might be arrived at regarding the share which each of these factors may have had in producing this divergence between the estimated and the enumerated population of 1901.

2. Notwithstanding that the number of *births* registered during the year under report exceeded the number registered in the preceding year by 6,682, the substitution of the census figures of 1901 for those of 1891 in calculating ratios, has had the effect of reducing the birth-rate of the former year below that of the latter. The recorded birth-rate for 1901 was only 32·07 against 38·37 for 1900; but, had the census figures of 1891 been used in calculating ratios in both years, the birth-rate of the year under report would have worked out to be 39·9 instead of only 32·07 per thousand of population. Similarly, as regards the *death-rate* for 1901; if this be calculated on the census figures of 1891 it will be found to be 27·03, or only slightly below that of the preceding year; whereas, calculated on its own census figures, it is 21·74. Such calculations may not be without use as a caution against attaching too much importance to the recorded ratios of births and deaths of the year as measures of its healthiness in comparison with previous years. It is only in Lower Burma that anything like a complete system as yet exists for the registration of vital statistics. In Upper Burma, births are registered only in 13 towns, whilst regarding the registration of deaths, the Sanitary Commissioner writes:—"Owing to population figures for the rural tracts in which deaths are registered not being available for Upper Burmah the statistics for towns can alone can be shown in this year's report." Much may be done in Burma, as in the Indian Provinces, to improve registration by the systematic

testing of the registers of births and deaths by house-to-house inquiries and by suitably punishing those whose duty it is to record births and deaths, but who persist in neglecting it. Quoting from the report:—"There has been some improvement in the inspection and check of birth and death registers during the year, but more energy in this direction is still desirable."

3. Beyond stating that the mortality from them was less than in the previous year, the report has little to say regarding the chief diseases. *Plague* has, so far, failed to establish itself in Burma, although during the year "five suspicious cases were reported by the Plague authorities." All of these occurred amongst passengers arriving in Rangoon by sea, and three of them proved fatal. They were followed by no cases amongst the indigenous population.

4. Vaccination, to judge from the returns for the past two years, has not only been making no progress, but has been rapidly losing ground. As compared with the large number of persons vaccinated in 1899–1900, the number in the following year decreased by over eighty thousand; and now again the numbers vaccinated during the year under report falls short of the previous year's numbers by over fifty thousand. And accompanying this decrease in the quantity of work there has been a corresponding falling-off in its quality. Whilst in 1899–1900 a percentage of 94·71 was recorded to be successful in cases of primary vaccination, this percentage has fallen in the year under report to 90·27. The large decrease in the numbers reported as successfully vaccinated is due in great part, or altogether, to the detection and suppression of false returns hitherto submitted by the vaccinators. In the Vaccination Report for 1899–1900, the Sanitary Commissioner wrote:—"It is very evident from district reports that there is a considerable amount of false work returned by vaccinators; and district medical officers' inspections show that there is an appreciable amount of utterly incompetent vaccination, as well as a large proportion of second-rate work." In last year's *Memorandum* we made the following comment on the decrease in the number of persons returned as having been vaccinated:—"Great as the decrease is, it is not to be deplored, if the Sanitary Commissioner is correct in assigning it to stricter supervision and to the check which the submission of falsified returns has received." In a country like Burma, in which the introduction of vaccination has to contend against the ancient and popular-practice of inoculation, in the protective effects of which against small-pox the people have implicit faith, it is of the first importance that only vaccine lymph of good quality should be used, and only properly trained vaccinators employed. One civil surgeon reports that in several villages in which vaccination had, in previous years' been readily accepted, the people were reverting to inoculation. Altogether, it seems clear that the position of vaccination in Burma is at present unsatisfactory, and that drastic reforms will be necessary before it can regain the confidence of the people. Amongst these reforms will probably have to be included the free elimination of incompetent and dishonest vaccinators, the appointment of a sufficient number of trustworthy inspectors, and arrangement for securing an adequate supply of genuine vaccine lymph. Civil surgeons could, and no doubt will, give invaluable assistance in restoring vaccination in their districts to a sound footing.

5. Of the *sanitary works* in progress during the year the most important were those for providing the two largest cities of the province, Rangoon and Mandalay, with pure water supplies. The water at present available in Rangoon has been repeatedly pronounced to be unfit for drinking purposes. The progress of the scheme for providing Mandalay with pure water is said to be slow, and yet the need for its completion has for years been acknowledged to be urgent. But the backward condition of Mandalay is not confined to its objectionable water supply. "The condition of affairs as regards the conservancy of the town," the Sanitary Commissioner declares to be "more than discreditable to municipal management." For the two towns next in size, Moulmein and Akyab, water-supply schemes have been prepared, and in the case of the former, "work will very shortly be commenced."

No. 7.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Central Provinces for 1901.

The population numbers of the census taken on the 1st of March, 1901, are used in calculating ratios throughout the report. During the 10 years following the taking of the census of 1891, the population of these provinces is shown to have decreased by 881,483, or from 9,554,513 to 8,673,030. By increasing the mortality and diminishing the number of births, the severe famines of 1897 and 1900, with their accompanying epidemics of disease, were chiefly concerned in bringing about this decrease. During these two famine years the number of deaths registered exceeded the number of births registered by 639,962. Had all the deaths which took place in those two years been recorded, their excess over the births would probably have been greater. For, if the population of 1901 be estimated by deducting the excess of deaths (401,983) over the births during the intercensal period 1891–1900, the result would be a total of 9,152,530; whereas actual enumeration shows it to be only 8,673,030. The difference between these numbers, viz., 479,500 would represent the number of unregistered deaths during the decennium, unless it could be accounted for by emigration. In the United Provinces of Agra and Oudh the enumerated population of 1901 is shown to have been less than the estimated population by a million and a half. The Sanitary Commissioner of those provinces confesses his difficulty in finding an adequate explanation of this wide divergence; but thinks it "probable that

deaths occurring among people on famine works were not fully reported, especially when cholera broke out in epidemic form." As similar conditions of famine and sickness existed both in the Central and in the United Provinces, and as in each of these Provinces the census population numbers of 1901 fell far short of the numbers deduced by substracting, in the one case, the excess of deaths over births from the census figures of 1891; and by adding, in the other, the excess of births over deaths; the divergence in both cases is probably due to the same cause or causes. The comment made by the Sanitary Commissioner of the Central Provinces regarding the wide difference between the estimated and the census numbers of the population is, that this difference of nearly half a million is not "such as to indicate anything seriously wrong in the reporting agency." One would have subscribed to this conclusion with less hesitation had it been found possible to furnish some sufficient explanation of the difference other than incomplete registration.

2. The vital statistics of the year under review are compared by the Sanitary Commissioner, not with those of the year immediately preceding, but with those of 1898. The reason given for the selection of 1898 is, that this, like the year under review, followed a famine year. The *birth-rate* for 1901 was only 28·83, and, with the exception of 1897, was the lowest recorded in these provinces for 20 years. The Sanitary Commissioner thinks the result is not surprising in view of the generally low vital condition of the population following in the wake of two successive famines. At the same time, the ratio of *deaths*, which had reached 56·75 per thousand of population, in the previous year, fell to 23·46 in the year under report.

3. The mortality from all the *chief diseases*, excepting small-pox, was much below that of the preceding year. Of deaths from *cholera*, only 49 were registered as compared with 63,114 in 1900. *Small-pox* alone continued to prevail in severe epidemic form, and was accountable for upwards of 6,000 deaths. Judged by the number of operations performed during the preceding two years, the progress of vaccination can scarcely be regarded as satisfactory. From a total of 509,323 in 1899–1900, the number of persons vaccinated fell in the following year to 455,397; and now, in the year under report, to 425,392. The decrease is attributed chiefly to the low birth-rate of the year and to the unfitness of many of the children to undergo vaccination in consequence of ill-health. The percentage of successful cases was nearly the same as during the previous year. Animal lymph, presumably applied direct from calf to arm, gave the highest percentage of successful cases, and this was closely followed by human lymph used from arm to arm; the percentage of success in the case of the former having been 95·63, and in the case of the latter 94·66. Glycerinated lymph is credited with a percentage of success of only 90·06, and lanoline lymph of only 88·81. The number of calves inoculated for the purpose of supplying vaccine lymph seems enormous when compared with the number of persons vaccinated with calf lymph. Of the 9,922 calves inoculated, the operation was successful in the case of 9,037, unsuccessful in 679; whilst in the case of 206, suppuration or excessive inflammation necessitated their rejection. But calves for the supply of lymph would appear to be obtained without difficulty in the Central Provinces, seeing that, notwithstanding the large number of calves vaccinated, the total cost incurred during the year in the cultivation of lymph was only Rs. 184-1-6.

4. During the year under report, whilst *plague* continued to prevail in the neighbouring provinces, the Central Provinces enjoyed complete immunity; not a single indigenous case of the disease having been reported in them during 1901.

5. The deaths attributed to *fever* decreased to about half the number recorded in the preceding year. The question of adopting measures for preventing, or diminishing, the prevalence of malarial fevers by waging war against mosquitos received much attention. Meantime, the Government continues to encourage the use of quinine by the people by reducing its price and increasing the number of agents for its distribution throughout the province.

6. "The expenditure on *Sanitary Works*, whether under the direction of the Sanitary Board or otherwise, was very small." Needless to add that this was owing to the exhaustion of public and private funds consequent upon a succession of adverse seasons.

No. 8.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Assam for 1901.

The Report, which fills the prescribed number of 12 pages, is clear and well-arranged. The small marginal tables introduced where necessary to explain the text are useful in saving constant reference to the figured statements in the Appendix. A paragraph briefly describing the chief climatic characteristics of the year and noting the prevailing food prices and rate of wages might have been of assistance in throwing light on the causes of the improved health of 1901 as compared with that of its predecessor, and with that of the preceding eight years.

2. There was a marked increase in the *birth-rate* and a still more marked decrease in the *death-rate* as compared with the corresponding rates for the previous year; but very little is said in explanation

of the causes of such increase and decrease. The birth-rate of the year under report rose to 33·98 from 32·31, the latter being the average for the preceding eight years, whilst the death-rate fell from an average of 34·93 in those eight years to 27·85. But there can be no doubt that, as a consequence of the defective state of the registration of vital statistics in the province, the birth and death-rates are understated.

3. The Sanitary Commissioner devotes a considerable portion of his report to the important subject of registration of vital statistics. The question has been repeatedly discussed, and remains much in the same position as hitherto. In the districts in which registration is effected by paid village watchmen, the record of births, and, in so far at least as their mere numbers are concerned, of deaths also, is carried out with some approach to accuracy. These village watchmen are under effectual supervision and control, being liable to be fined or otherwise suitably punished for neglect of their duties. But, unfortunately, these paid agents are employed only in the two districts of the Surma Valley and in one of the six districts of the Brahmaputra Valley. In the remaining five districts of the latter, unpaid and irresponsible agents, locally known as *gaonburas*, or head-men of villages, are entrusted with the collection of vital statistics and perform this duty badly. The results obtained clearly illustrate the comparative value of each of the two kinds of agents. Whilst the three districts in which paid village watchmen are employed return birth-ratios varying from a maximum of 44·25 to a minimum of 35·38 per thousand of population, the five districts in which unpaid *gaonburas* are expected to carry out the work of registration, return rates varying from a maximum of 31·36 to a minimum of only 26·28 per thousand of population. "Indeed the figures for Kamrup, Nowgong, Sibsagar, and Lakhimpur may be looked upon as practically worthless, and those for Darang are very little better." It would obviously be useless to submit such figures to a minute analysis, and unsafe to draw from them conclusions regarding the health conditions prevailing in the districts for which they are recorded. The Government are fully aware of the unreliable nature of the vital statistics recorded in the districts in which unpaid agents are employed for their collection, and anxious to effect their improvement. After remarking that their vital statistics would lead to the conclusion that the two healthiest districts in the province had the lowest birth-rates, the Government add :— "These figures indicate that the vital statistics of Assam are most inaccurate, especially in the Brahmaputra Valley, where there is no paid agency for collecting them. The Officiating Chief Commissioner would be reluctant to add to the subordinate official staff of the province simply for statistical purposes, but it may be possible to improve matters by attaching some remuneration to the office of village head-men (which now carries no emolument), and this question will be considered." Without an approximately accurate record of its vital statistics, neither can the sanitary wants of the province be estimated, nor the effect on health of the introduction of sanitary improvements gauged with any approach to certainty. At present, these statistics are so inaccurate as to be not only worthless but liable to mislead.

4. Of the chief diseases *cholera* showed a remarkable abatement in severity. The number of deaths due to it was less than a third of that recorded under the same head in the previous year; and less than half of the average number during the previous fifteen years. To what cause or causes this lessened prevalence of cholera was due no attempt is made to explain. Cholera prevalence being considered by many to be influenced directly or indirectly by the rainfall, it might be useful in future reports to give some account of the character of the rainfall of the year, noting whether it was excessive, normal, or defective in quantity, and whether it was seasonable and regularly distributed or otherwise. The cholera death-rate on tea-gardens again exceeds the general provincial rate, the former having been 2·17 and the latter only 1·42; but taking into account the very incomplete state of birth and death registration amongst the general population, and what may be assumed to be the comparatively accurate record kept of deaths on tea-gardens, too much importance need not be attached to a comparison of these ratios. The number of tea-garden coolies imported during 1901 was less than in any one of the preceding 13 years; and the cholera death-rate amongst them "whilst in transit from Goalundo to the post nearest to the place of their employment," has been lower in three only of those 13 years. Possibly some connection might be traced between the number of coolies annually imported and the percentage of those attacked by cholera during transit. Referring to the marginal table to paragraph 28 of the Report, it will be seen that the four years returning the largest numbers of coolies imported were all of them years of abnormally high ratios of cholera mortality; and that the four years returning the smallest numbers of coolies imported were all of them years of low ratios of cholera mortality amongst the coolies during transit. These figures may not be without their significance.

5. *Small-pox* was considerably more fatal than in either of the preceding two years, but except in one district, the death-rate due to it was less than one per thousand of population. The cause of the greater prevalence of the disease in the district in which the mortality exceeded one per thousand is believed by the District Medical Officer to have been the diffusion of small-pox infection by the practice of inoculation. The Sanitary Commissioner agrees with the District Medical Officer mentioned in proposing to extend the Act for preventing inoculation to the whole of the district of Sylhet. The prevention of inoculation would be justifiable only if vaccination were first placed within the reach of every one of the inhabitants of the district. The prejudice in favour of inoculation might perhaps be tolerated were only those who prefer and practise it the sufferers, but unfortunately its chief victims are their neighbours, and generally their poorer neighbours, who are unable to pay the somewhat heavy expenses connected with the operation. The numbers vaccinated in the province show a considerable increase over those for the preceding year, and a large increase over the average for the 15 years 1884–85 to 1898–99. The reported percentage of successful cases of primary vaccination was as high as 97·48, and in re-vaccination 81·09. "The quality of the lymph was generally excellent throughout the year," but further experience would appear to show that Colonel Campbell was somewhat too sanguine in his estimate of the length of time during which glycerinated lymph would retain its activity unimpaired. In his Annual Report of the Animal Vaccine Depôt at Shillong for the year 1899–1900, he writes :—"Two thousand tubes

manufactured on 11th February and 15th February, 1900, were forwarded to the Principal Medical Officer and Sanitary Commissioner, Assam, to be kept for experiment to see if lymph will keep in the plains through the hot weather if not exposed to sunlight or heat, *i.e.*, if simply shut up in a wooden box. I believe this will prove to be the case." In his Report on Vaccination for 1901–02 the Sanitary Commissioner, after detailing the experiments conducted with glycerinated lymph, writes :—"I think it may therefore be concluded that the glycerinated lymph as stored in hermetically sealed tubes will not keep for more than four months, even in a cool place, and it begins to deteriorate after three months' storage. It has further been ascertained that it will not keep for two months in the plains in the hot weather, and probably not for more than one." It is satisfactory to learn that the mortality among the calves used for the supply of lymph has been reduced to less than half that reported in the previous year. Only 12 calves died in the year under report, as compared with 26 in the previous year, and with 41 in 1899–1900.

6. The mortality from *fever* was somewhat greater than in the previous year, but not above the average for the 15 years 1884–1898. As the Sanitary Commissioner had predicted, the form of fever known as *kálá-ázár* continues steadily to decrease in Assam. It now only exists to any serious extent in two districts of the Brahmaputra Valley, and even in these it is steadily abating. Unfortunately it is beginning to show signs of activity in the Surma Valley. Quoting from the Government review of the report—"But whilst loosening its grasp of the districts in the Brahmaputra Valley it has effected a lodgment in Sylhet, where the density of the population is 412 persons to the square mile as compared with 108 for the Brahmaputra Valley."

7. Of *Sanitary Works* it is stated that no one of magnitude was undertaken during the year, and no provincial scheme of any importance was under consideration. What of funds were available for sanitary improvements in rural areas were principally expended in providing better water-supplies; but in the concluding words of the Government resolution on the Report, "It must, however, be realised that the funds available for village sanitation are very small."

13th May, 1903.

No. 9.

Memorandum by the Army Sanitary Commission on the Rajputana Sanitary, Vaccination, Dispensary and Jail Report for 1900.

The report on the working of the several departments above enumerated has been reduced to a few pages of summary comment on each. The history of sanitation in Rajputana, with its population of twelve and a half millions, during a year of excessive sickness and mortality is compressed within less than half a dozen pages, not counting the figured statements. The year was one of abundant rainfall. In Ajmere the amount of rain registered exceeded 25 inches, as compared with only 10 in the preceding year; and in Bewar 23·47 as compared with only 5. "The harvests, generally, were good, but the people, enfeebled as they were by past privations, fell an easy prey to the epidemics of cholera, malarial fever, dysentery and small-pox that ravaged the province during the autumn of 1900."

2. As in previous years, the only part of Rajputana which furnishes vital statistics having any claim to accuracy is Ajmer-Merwara. The population of this district, according to the census of 1891, numbered 542,368 out of a total for Rajputana of upwards of twelve and a half millions. The *birth-rate* in Ajmer-Merwara for the year under report fell to 14·67 per mille of population from 31·40 in the previous year; whilst the death-rate rose to no less than 119·97 from 33·21. In other words, for every birth recorded during 1900 there were more than eight deaths. The census figures of 1891, now available, show that during the decennium 1891–1901 the population of Ajmer-Merwara decreased by 66,028 or 12·17 per cent., whilst during the preceding decennium it had increased by 17·72 per cent. The Residency Surgeon and Chief Medical Officer writes :—"The mortality of the famine year 1900 was 65,067. The excess beyond the average, viz., 49,967, may be taken as the minimum number whose deaths were due either directly or indirectly to famine and its attendant diseases." Striking as these figures are, there is no doubt that many deaths escaped registration during the famine period, "especially when people deserted the famine camps as soon as cholera appeared, and many of the wanderers died by the wayside in consequence." If, during a year of so great distress, registration of births and deaths is acknowledged to have been incomplete in a division of the country under direct management of Government, little reliance can be placed on returns of vital statistics furnished by the Native States. "Registration has been attempted in 18 Native States as in the previous year, but so far with unsatisfactory results. At the time of the Famine Commission in Ajmer in February last, an attempt was made to get statistics similar to those supplied to the Commission from the Ajmer-Merwara District, but the universal reply was, 'Information not available.'"

3. *Chief Diseases.—Cholera*, from which Ajmer-Merwara had been almost entirely free during the previous year, prevailed in severe epidemic form throughout the district. Whilst in 1899 only one death was attributed to it, the number of cases recorded during the year under report was 5,621 and the deaths 4,841. The number of deaths ascribed to cholera in the Native States was 28,719; but if the disease was not less fatal in these States than in the Ajmer-Merwara district, the number must be

understated. If cholera carried off 4,841 persons out of a population of half a million in Ajmer-Merwara, it is scarcely probable that it carried off only 28,719 out of a population of over twelve millions. If the recorded number were doubled it would probably still fall short of the actual number. The measures adopted with a view to arrest the progress of the epidemic are thus mentioned: "All necessary precautions were taken throughout the Ajmer-Merwara District in the way of sanitation and disinfection of wells to stop the disease, and cholera pills were distributed in all villages." A more detailed account of the epidemic and of the measures found to be most effectual in controlling it might have been useful in dealing with future outbreaks.

4. *Small-pox* prevailed in severe epidemic form in Ajmer-Merwara, causing 2,610 deaths, or a ratio of 4·8 per thousand of the population. In the Native States the number of small-pox deaths registered was only 3,051, or 0·25 per mille of population; but this number probably represents but a fraction of the actual mortality from this disease. In Annual Vaccination Statement I. the average ratio per thousand of the population of Ajmer-Merwara successfully vaccinated during the previous five years is recorded to have been 34·08; and in the Native States only 26·13; so that, if the mortality from small-pox bore any proportion to the protection afforded by vaccination, the people of the Ajmer-Merwara division should have suffered less instead of sixteen times more severely than those of the Native States. During a year of excessive sickness it was only to be expected that there would be a decrease in the number of persons vaccinated. The number of children was abnormally small, and many of them were so weakly as to be unfit to undergo vaccination. But, in spite of the disadvantages under which vaccination was carried on during the year, the same astonishing ratios of successful cases as in previous years are recorded. In Ajmer-Merwara the percentage of successful cases claimed was 99·20; and in no fewer than four of the Native States every primary case of vaccination was returned as having been "successful."

5. In Ajmer-Merwara, the only portion of Rajputana for which reliable vital statistics are available, *malarial fevers* are credited with a death-rate of no less than 81·56 per thousand of population as against a mean of only 19·52 for the previous five years. The mortality due to *dysentery* and *diarrhœa* rose to 15·90 per thousand of population from a mean during the previous five years of 1·12. The province fortunately escaped during such a calamitous year an epidemic of *plague*. Only two cases, both of them imported, were reported during the year.

6. No new *sanitary work* of importance appears to have been undertaken during the year. The Chief Medical Officer reports that "in several of the Native States the Medical Officers do not take an active part in the work of sanitation and the registration of vital statistics of the Head-quarters stations to which they are accredited, and these important matters are entirely in the hands of Native officials, with unsatisfactory results."

7. The section of the Report dealing with the working of *Dispensaries* during the year calls for no special remark.

8. Owing to the prevalence of famine, the *Jail* population of the province was greater than in the previous year. The sickness and mortality amongst the prisoners were enormous. In the Ajmer jail the average sick-rate rose from 6·24 in the previous year to 14·57; and the death-rate from 5·32 to 77·32. In the jails of the Native States, whilst the cases treated more than doubled, the number of deaths increased from 155 in the preceding year to no less than 1,420 in the year under report, or to a ratio of 215·04 per thousand prisoners. In one jail, with a daily average strength of 230·59 prisoners, the number of deaths was 416, or at the rate of 1,804·07 per thousand of strength. This terrible mortality was, no doubt, in main part due to the bad state of health of the prisoners at the time of their admission into jail; but the overcrowding, defective drainage and construction mentioned in the Report must also have contributed to swell the sick and death rates.

9. *Summary.*—Exigencies of space have reduced the Report to a brief commentary on the statistical returns. The health conditions of 1900 were exceptional. Whilst the birth-rate fell to less than half that recorded for the previous year, the death-rate rose to no less than 119·97 per thousand of the population. Under normal conditions the death-rate rises and falls with the rise and fall of the birth-rate; but in the year under report the abnormally high death-rate accompanied an abnormally low birth-rate. The causes of this disturbance of the ordinary relation between birth and death ratios were famine and destructive epidemics of disease. The account given of the epidemics of cholera, fever, and small-pox are meagre. As might have been expected, vaccination work decreased during such a year; but there is a repetition of the extraordinarily high percentages of successful vaccine operations hitherto recorded in Rajputana. Under the influence of famine, the numbers of the jail population greatly increased, and the amount of sickness and mortality amongst the prisoners, more especially in the Native States, was excessive. Although abnormal sickness and mortality were mainly due to the famine and the epidemics of disease from which the province suffered, the overcrowding and defective sanitary conditions existing in some of the jails doubtless had a share in their causation. In one jail the almost incredible ratio of 1,804·07 deaths per thousand of the average strength of the prison population is recorded. Such figures are of themselves sufficient indication of the need for strenuous endeavour to ameliorate the lot of the prisoners in some of the Native States.

24th January, 1903.

No. 10.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Madras for 1901.

The volume containing the Reports of the Sanitary Board, Sanitary Commissioner, and Sanitary Engineer for 1901 appears in a much attenuated form. Each of the three reports has now been reduced within the limits prescribed by the Government of India. During the year the Sanitary Board scrutinized the plans and estimates of 85 sanitary works of the total estimated value of nearly fourteen and a half lakhs of rupees. Among the new type designs issued is one for a cheap description of latrine for rural purposes, and another for a private house latrine. The former was evolved after prolonged consideration by the members of the Board, and claims to be based on sound sanitary principles. If the latrine is found in practice to be efficient and to satisfy the requirements of the rural population, an important step will have been made towards overcoming one of the chief difficulties hitherto met with in the effort to keep clean Indian villages and their environment. The publication of these type designs will enable the sanitary authorities in other Indian provinces to profit by the useful investigations and inventions of the Sanitary Board of Madras.

2. The year was one of increased mortality and decreased fecundity: in other words, it was unfavourable to the public health. The rainfall recorded for the Presidency, as a whole, was 3·5 inches above the average of the ten years ending 1898; but from such a statement no deduction can be drawn regarding the fall in particular districts. It is shown that notwithstanding the general rise in the average rainfall for the province, there was a deficiency in some districts amounting to as much as 28·7 per cent. of the decennial average. The staple food grains, *cholam*, *raggi*, and *cumbu*, cost on the average respectively 15·6, 15·7, and 15·1 seers per rupee, against a decennial average of 20·4, 22·5, and 20. Unless so great a rise in the price of food was accompanied by a corresponding rise in wages the people must have felt the pressure of hard times severely. To this pressure the unfavourable health statistics of the year were doubtless in great part due. The Sanitary Commissioner says:—"The rate of wages is slowly increasing." If procurable, some figures to show the movement in the scale of wages of the labouring classes might usefully accompany the record of prices of food grains.

3. The census numbers of 1901 are used throughout the report in calculating ratios. The "natural increase" of the population of the Presidency since the previous census was taken in 1891 was 2,572,646, or at the rate of 6·99 per mille, excluding Feudatory States. This shows a remarkable decrease when compared with the "natural increase" of 4,879,894 in the previous intercensal period. As the Sanitary Commissioner points out, if the census figures of 1891 are used in the calculation of birth and death rates for each of the succeeding intercensal years, there will be a constantly increasing error in the resulting ratios which will reach its maximum in the last year of the series. With the introduction of the new census figures in 1901 the error will be rectified, but only to recommence and keep increasing during succeeding years until next census is taken in 1911. It is true that the method of calculating birth and death ratios on the census figures during the entire intercensal period has the effect of showing an apparent increase in these ratios which might be erroneously credited to improved registration, provided that the population increased from year to year. The Sanitary Commissioner says, "This would at all times be avoided by use of 'estimated populations.'" The method of "estimating" the population of a country during each of the intercensal periods is based upon the assumption that the rate of increase, or in exceptional cases decrease, will be the same during the coming intercensal years as it had been during the immediately preceding intercensal period. But in the case of the Madras Presidency the increase of the population numbers between the taking of the census of 1881 and the taking of the next in 1891 amounted, as already stated, to 4,879,894. Consequently, if the population of each year succeeding the taking of the census of 1891 were "estimated" by adding a tenth of this number to the figures for the preceding year, it is obvious that the estimated population numbers would be largely in excess of the actual numbers; for the census of 1901 shows that the increase during the years since the previous census was taken was only 2,572,646, or but little more than half the increase during the preceding intercensal period. If, therefore, the ratios of births and deaths had been calculated upon the population numbers of each of the intercensal years succeeding 1891, "estimated" as described, they would still have erred, although in an opposite direction; they would, in fact, have been nearly as much in defect as those calculated on the census numbers of 1891 are in excess of the real ratios.

4. The *births* during the year under report show a decrease of 113,450, and the *deaths* an increase of 25,281 as compared with the numbers recorded in the preceding year; but yet the total births exceeded the total deaths of the year by 139,609. As in the previous year, the birth and death rates recorded in town circles are much in excess of those recorded in rural circles. Whilst the town circles record a birth-rate of 30·7, the rural circles record a birth-rate of only 24·6 per thousand of population, according to Table I. of the Appendix. This is a reversal of the relation which the birth-rate of towns ordinarily bears to that of the country. The Sanitary Commissioner offers an explanation which, he thinks, might account for the greater fecundity in towns. "That the town population of the Presidency should have been less influenced than the rural as to fecundity by the high price of food-grains, seems to support the view that the pressure was chiefly upon the lowest classes of the agricultural population." But if the pressure of the high price of food-grains was chiefly on the lowest classes of the agricultural population, it might be expected that the mortality amongst these would, as a consequence, be higher than amongst the inhabitants of towns, on whom the pressure was less, or at all events that it would not be abnormally low. On the contrary, however, whilst the death-rate recorded in town circles was 32·7, that recorded in rural circles was

only 20·4. As suggested in our *Memorandum* for 1900, an explanation of this abnormal contrast between the birth-rates of rural and town circles in Madras might perhaps be found in the more defective way in which registration was carried out in the former than in the latter. The fact that "in all municipal areas registration of births and deaths was compulsory" would support this suggestion. Moreover, a reference to the vital statistics of the neighbouring provinces of Bengal and Bombay, for the same year, shows that the birth-rate of the former province was only 22·74 per mille in urban, as compared with 39·39 in rural circles; and of the latter province 22·72 as compared with 25·27. The birth-rate, therefore, in the two neighbouring provinces follows the usual rule of being higher in the country than in towns; whilst in the Madras Presidency it is unusual in being lower in the country than in towns.

5. *Cholera* was exceptionally fatal during the year, accounting for 91,307 deaths. The Government, in requesting that in future reports the relation between the prevalence of cholera and the existence of a protected water-supply should be noticed in more detail, point out that whilst the cholera mortality in all towns taken together was 2·7 per mille, the ratios in those which had a protected water-supply was 1·97.

6. *Small-pox* mortality shows a slight decrease as compared with that recorded in 1900, but is still high. Of the 26,202 deaths recorded, no fewer than 8,029 occurred among children of less than one year of age; whilst 7,131 occurred among children between one and ten years. These results are only those to be expected when it is seen that, whilst there were 935,749 births recorded during the twelve months of the calendar year, there were but 354,527 successful vaccinations of children under one year of age in the twelve months of the official vaccination year. Satisfactory features of the year's vaccination work are the increase of 67,223 operations over the number for the previous year, and the increase in the number of operations performed by each vaccinator from 1,473 to 1,584. Important as the increase of the vaccination establishment would be to meet the growth of the population of the Presidency, perhaps a still more important need is the improvement of the quality of the vaccine lymph. From the table given in paragraph 10 of the Vaccination Report, it appears that, of 1,159,880 successful operations, 414,476 were performed by the staff paid from local funds; and that in these latter cases glycerinated lymph, locally prepared in different centres, was employed. The resulting percentage of successful cases following the use of this lymph was only 86·9, as compared with 98·4 obtained in the 216,606 cases vaccinated by the calf-to-arm method by the same staff of operators. Although the results obtained by municipal vaccinators using glycerinated lymph were better than those obtained by the local fund vaccinators, they were still far less favourable than those following the use of lymph applied directly from the calf to the arm. After remarking that the quality of work done is not so good as it was ten years ago, the Government add:—"The marked fall in the measure of success obtained with glycerinated lymph is a matter of serious importance, which has not received adequate notice from either the Inspector of Vaccination or the Sanitary Commissioner, but the Government trust that the opening of the Vaccine Institute will result in the supply of lymph of uniform and reliable quality."

7. This Presidency has hitherto maintained a successful combat against *plague* invasion from Bombay and Mysore; but the returns for 1901 would appear to show that the defence is at length being overpowered. The number of attacks arose from 895 in the preceding year to 3,960 in the year under report. The "passport system," which has hitherto successfully resisted the spread of plague, is still being persevered with, and the Sanitary Commissioner shows good reasons for claiming that numerous localities have been saved from plague by the prompt discovery of cases of the disease.

8. As usual, *fevers* were the most fatal of all the diseases. In the paragraph devoted to these, the remarks regarding typhoid fever are of interest in connection with the question of the prevalence of this disease amongst the natives of India. Colonel King writes:—"A diagnosis of typhoid fever is common enough on the Nilgiris and at times in Malabar and South Canara, but it is rare in the plains, although I have personally seen cases from time to time in the Trichinopoly and Kurnool districts." He adds:—"Lieutenant-Colonel Wilkins, District Medical and Sanitary Officer, Malabar, has sent me a list of 73 cases treated in the various hospitals in his charge during the last ten years." These remarks support the conclusions regarding the comparative liability of Europeans and Natives to typhoid fever arrived at from an examination of the records of sickness and mortality in the Native Army and Jails of India. Quoting from our *Memorandum* on the Report of the Sanitary Commissioner with the Government of India for 1900:—"Reliable statistics of the disease amongst the natives of India are mostly limited to those furnished by the Native Army and Jails. Whilst the recorded deaths from enteric fever numbered 289 out of a strength of 60,553 European soldiers, there were only 18 in the Native Army, with rather more than double the strength, and only 17 out of an average strength of 121,511 prisoners."

9. The water-works extension at Trichinopoly, and the Vizagapatam and Cocanada water-works, which had been commenced in 1900, appear to have been the only sanitary works of importance under construction during the year. The Sanitary Commissioner thinks that, unfortunately, it is not probable that much advance in large sanitary works, such as those for water-supply and sewage, will be recorded in future sanitary reports of this Presidency, having regard to a recent ruling of the Government of India, that grants-in-aid will not be given to local bodies. The important scheme for training a sufficient staff of Sanitary Inspectors for the requirements of Municipalities and Local Boards is being successfully carried out.

13th May 1903.

No. 11.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bombay for 1901.

The Report is mostly a repetition in narrative form of the statistical tables attached to it as an appendix, and consequently affords but little matter for comment. In the Government review it is disposed of in a page ; whilst the accompanying Vaccination Report is considered to call for no special remark. Questions connected with the origin and spread of the diseases which were the chief causes of mortality, such as fever, plague and cholera, are scarcely touched ; and there is but little account given of the measures adopted with the object of checking the progress of such diseases. A brief record of the experiences and observations of the medical officers engaged in the investigation of the causes of sickness and mortality prevalent during the year, and in devising and carrying out measures for dealing with them, could not have failed to be useful.

2. The year under report was less unhealthy than its predecessor. In spite of the great increase of plague, the total mortality fell to nearly half that recorded in 1900. Of the chief meteorological features of 1901, no account is given beyond the remark that the rainfall was below the average in all of the districts except two, and that in others it was only about half the annual average. During the previous year the deaths exceeded the births by no fewer than 813,121 ; and this year again they are in excess by 220,487 ; so that, leaving out of count immigration or emigration, the population of the province has undergone a decrease of upwards of one million in the two years 1900 and 1901. The *birth-rate*, 25·19, was the lowest recorded for any one of the last ten years ; whilst the *death-rate*, 37·12, was somewhat higher than the decennial mean.

3. The number of deaths from *cholera*, which had suddenly increased from 8,579 in 1899 to 163,889 in the following year, as suddenly fell in the year under report to 13,600. According to the Government review, "famine conditions prevailed throughout the year 1901 in Gujarát and the Northern Deccan, owing to the partial failure of the monsoon both in 1900 and 1901." Turning to Annual Form No. VI. it is seen that, in spite of its having been afflicted by famine, Gujarát is one of the only two Registration Districts of the province that did not record a single death from cholera ; another illustration of what has been more than once observed during recent famine years in India, that there is no necessary connection between cholera and famine prevalence. Nor did "the partial failure of the monsoon," with the deterioration of the water-supply which may be assumed to have resulted, prove sufficient to light up an outbreak ; although the impurity of the drinking water consequent upon a deficient rainfall is not infrequently assigned as a cause for cholera. These conditions, famine and impure water, although known to be favourable to the development and spread of cholera, appear to be incapable even when, as in this instance, acting together, of originating an outbreak in the absence of the specific exciting cause of the disease.

4. The deaths from *small-pox*, which had been more numerous in 1900 than in any one of the previous ten years, fell during the year under report to nearly half. Of persons primarily vaccinated there was a decrease in number of 115,961 as compared with the number for the previous year, as well as a decrease of 23,372 re-vaccinations. The decrease is attributed to "a low birth-rate, consequent upon the incidence of famine and plague" ; and to opposition to vaccination in Sind. In this Presidency humanized vaccine lymph is still chiefly used ; and, except in the Sind Registration Circle, it yielded a higher percentage of successful cases than animal lymph. In the Presidency Circle alone no vaccinations were performed with human lymph ; and, here, animal lymph was followed by a much lower percentage of success than the humanized lymph used throughout the rest of the province. Glycerized lymph was only used in 583 cases and yielded the low percentage of 73·42 ; the lowest percentage of success following vaccination with humanized lymph having been 86·81 and the highest 93·37. Altogether, as the Sanitary Commissioner observes, "the present year has been a very disastrous one for vaccination." It is of the very first importance that arrangements should be made for the provision of an adequate supply of good vaccine lymph. In India, some of the provincial vaccination departments, in their zeal to introduce the changes adopted during recent years in the practice of vaccination in Europe, have omitted to take the preliminary measures necessary for securing the successful working of the altered methods. Until the arrangements are complete for providing calf lymph prepared by admixture with glycerine in such a way as to preserve its activity unimpaired, and to supply it in sufficient quantity, it would be expedient to continue the use of lymph taken direct from the calf. But here again, there is not infrequently a difficulty in procuring calves for the supply of the required quantity. In the last resort, however, human lymph is available ; and the result of a century's experience of the almost exclusive use of human lymph has been that, except in rare instances, and those mostly due to carelessness, no ill effects have been known to follow its employment. Hitherto, in India, glycerized lymph has not yielded so successful results as human lymph, if those reported from Assam be excepted.

5. Whilst the mortality attributed to *fever* decreased to nearly half that recorded in 1900, the number of deaths from *diarrhœa* and *dysentery* fell from 218,243 to 60,198. The enormous mortality from bowel complaints in 1900 may be taken as some measure of the severity of the famine in that year. Of the destructive epidemic of *plague* very little is said in the report beyond the remark that the mortality due to it was the highest hitherto recorded. The number of deaths reported from plague was 33,196 in the previous year, and in the year under report 128,259. The ratio of deaths registered under the heading "other causes," which began to increase from the time of the appearance of plague in the Presidency in 1896, still goes on increasing. In previous *memoranda*, reasons have

been given for believing that this increase is due rather to causes connected with plague prevalence than, as the Sanitary Commissioner suggests, to improvement in the registration of deaths according to their causes.

6. In the Report of the Sanitary Board it is stated that "owing to plague and famine, local bodies were unable during the year to take up any important sanitary projects." An experimental sewage farm has been established with the object of ascertaining if the sewage of Poona city can be profitably disposed of in the fertilization of the soil and the raising of crops, instead of being wastefully and perhaps injuriously discharged into the river. The result will be watched with much interest by the municipal authorities of other cities in which the question of the best means for the disposal of sewage still remains unsettled.

7. The Report of the Port Health Officer of Bombay is, this year again, a record of strenuous and successful endeavour to prevent the dissemination of infectious diseases by ships leaving the port. Compared with its predecessor the year was one of much lower mortality from cholera and small-pox; but plague was more prevalent. In Bombay City 18,736 deaths from plague were recorded during the year; yet amongst the crews and passengers, numbering over eight hundred thousand, on board the inspected ships leaving Bombay, only three persons who could have been infected before sailing were reported to have subsequently developed the disease.

No. 12.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner for the Hyderabad Assigned Districts for 1901.

The year, which was an unusually healthy one, has its sanitary history sketched in a Report covering only four pages. The lowness of its birth and death rates was in some degree the consequence of the conditions of famine and sickness which had prevailed in the preceding year. Whilst the usual effects of antecedent famine on fecundity are indicated in the low birth-rate, the death-rate is also low, because of the accompanying low birth-rate; and also because, in the words of the Sanitary Commissioner, "most of the aged, weakly, and sickly had succumbed to the famine privation of the previous year." It might have been added that the very young, as well as the very old, succumbed in unusual numbers to the privations of the previous year. The infant mortality in that disastrous year reached the enormous ratio of 478·5 per thousand. As a result of this excessive mortality amongst infants in 1900, and of the small number of children born during 1901, the proportion of infants in the latter year, or in other words of those most "liable to death," was unusually low. This must have combined with the other causes mentioned to lower the death-rate from 82·7 in 1900 to only 27·6 in the year under report. Influenced as, of course, it chiefly was by the antecedent conditions prevailing in 1900, the birth-rate fell from 31·3 in 1900 to 30·8 per thousand of population.

2. An account is given of the measures taken to ensure the careful registration of vital statistics. The census figures of 1901 bear remarkable testimony to the efficiency of the registration of births and deaths in this province. When the births registered since the previous census of 1891 are deducted from the deaths registered during the same period, and the number (150,803) by which the deaths exceeded the births is subtracted from the population figures of 1891, it is found that the population numbers of 1891, thus estimated, differ from the numbers ascertained by the census by only 15,324. The number of registers of births and deaths inspected was somewhat smaller than in the previous year; but the inspection was evidently more thorough. The system of checking the entries in the registers by house-to-house inquiry is tedious and laborious; but in no other way can errors be detected with certainty.

3. *Cholera*, which carried off no fewer than 18,375 persons in 1900, was almost absent from the province; only 17 deaths having been attributed to it during the year under report. To the paragraph describing the slight outbreak which caused the deaths of 16 out of the total number of 17 deaths, the Sanitary Commissioner adds:—"Permanganate of potash was freely employed as usual for disinfection of all wells and polluted sources of water supply." This use of permanganate of potash during times of cholera prevalence has, in many parts of India, come to be more or less a matter of routine. And yet, there is little, if any, evidence of a reliable nature to show that the permanganate exercises a specific effect in destroying the cholera poison in the wells and other sources of water supply to which it is added. Most of the evidence brought forward in support of the belief that cholera outbreaks are cut short by the disinfection of the contaminated water supplies by the permanganate is furnished by hospital assistants, vaccinators, and others more or less untrained in scientific methods of observation. Unless there is reasonable proof that this chemical is entitled to the credit given it of destroying the cholera poison in sources of drinking water, its routine employment may not only be useless but may do harm by withdrawing attention from more important measures for providing and permanently protecting pure water supplies. Moreover, until it has been conclusively shown that the permanganate produces the results claimed for it, the scanty resources of district boards and municipalities might be better spent on sanitary improvements, which experience

has demonstrated to be effectual in diminishing the liability of villages and towns to disease of all kinds, including cholera. In connection with this question reference should be made to the report of the Inspector-General of Prisons of the United Provinces of Agra and Oudh for the year under report. As the result of an experiment conducted by a medical officer, under conditions calculated to exclude error, he arrived at the conclusion that the use of the permanganate of potash in disinfecting the water used by the prisoners in the Central Prison at Lucknow, during the recent cholera outbreak there, exercised no appreciable effect on the progress of the disease. The subject is more fully discussed in our *Memorandum* on the Report of the Sanitary Commissioner of Bengal.

4. The deaths from *small-pox* decreased from 830 in the previous year to 190, and was equal to a ratio of only ·07 of the population of the province. The diagram on page 2 of the Vaccination Report illustrates very effectively the protective influence of vaccination against death from small-pox. The use of lanolinated vaccine lymph during the year proved very successful. Whilst it was followed by as high a percentage of success as the fresh calf lymph in use during the preceding year, it cost less, and on account of the greater convenience with which it could be used, admitted of a reduction in the strength of the vaccination establishment. Each vaccinator was able, during the year, to perform by means of it as many as 2,867 operations.

5. The mortality from *fever* and *bowel complaints*, which had been excessive during 1900, fell much below the mean ratio of the previous five years.

6. The expenditure on *drainage* and *water supplies* by municipalities seems inconsiderable ; less than four thousand rupees on the former and less than seventeen thousand on the latter. But these sums have to be regarded relatively to the size of the province, which, in point of population, is less than a single one of several districts in Bengal, and of at least one district in the United Provinces of Agra and Oudh.

13th May, 1903.

No. 13.

Memorandum by the Army Sanitary Commission on the Administration Report of the Town of Calcutta for 1901-02.

During the year the Administration Departments of the Municipality were reorganized. The partition of the town into four districts, each with its own separate Health Department and Engineer Department, should facilitate closer supervision of sanitary details and admit of more prompt action being taken in remedying sanitary defects than when the town was dealt with as a whole. The charge of the conservancy of the town has been withdrawn from the Health and placed under the Engineer Department. Whether this change will conduce to greater efficiency remains to be seen. At first it is likely to lead to an increase of correspondence, and perhaps to occasional friction between the two Departments. A still more important change is made in the position which the Health Department is in future to hold relatively to the Building Department. "Under the new scheme the action of the Health Department is restricted to action in connection with existing nuisances." The expediency of such restriction is more than doubtful, if its purpose is to deprive the Health Officer of the opportunity of expressing, in his capacity of sanitary expert, an opinion regarding the sites chosen for new buildings, and the suitableness or unsuitableness of the buildings themselves for the purposes for which they are intended. To neglect of the repeated warnings and remonstrances of the Health Officer in the past is due in no small degree the necessity for demolishing at vast cost blocks of buildings now pronounced to be so insanitary as to be incapable of being effectually dealt with in any other way. Yet the paragraph defining the position of the Health Officer concludes in the following words :—"In the matter, however, of dealing with applications for sanction to erect or re-erect not only domestic buildings, but also privies, cattle-sheds, and stables, the new Building Department has full executive control." Fortunately, this decision has not escaped the notice of the Government. In the review of the report by the Lieutenant-Governor of Bengal we read :—"The Health Department is now altogether dissociated from the Building Department, and it is a question whether this is altogether desirable. It appears that the Health Department is restricted to independent action in connection with existing nuisances only, but special cases must sometimes arise where the opinion of the Health Officer would be valuable in regard to applications for new buildings. If it be the case, as stated in the report, that the insanitary condition of certain areas in Calcutta is due more to structural defects than to any other cause, the importance of intimate relations between the Building and Health Departments is obvious, and the Acting Lieutenant Governor feels no doubt that the matter will receive attention." Possibly, the interference of the Health Department might be considered by the Building Department to be occasionally somewhat meddlesome or obstructive ; and it might tend to lessen the need for such interference if type designs of buildings were prepared in concert with the Health Department, and if no buildings were erected which did not conform, in principle at least, with such designs. To ignore, or rather, to deliberately dispense with, the advice of the Health Officer regarding the erection of buildings would be to court in the future a repetition of the mistakes of the past.

2. A *birth-rate* of only 10·7 per *mille* of population was recorded. Even taking into account the disproportion between the sexes in the constitution of the Calcutta population, 562,596 males to 285,200 females, there can be no doubt that the real birth-rate is higher than that recorded. The division of the city into four districts, each with its own separate Health Department, will, it is

expected, lead to much-needed improvement in the registration of vital statistics. The *death-rate* recorded for the year under report was 38·1 per thousand of population; and this is described by the Health Officer as "abnormally high." It is, however, considerably lower than in the preceding year, when it was 43·5. Taking into account the constitution of the population of Calcutta, with its small proportion of infants, and high proportion of adult males, a very low death-rate might be expected; whereas, in spite of its supply of filtered drinking-water, its drainage system, still far from completion it must be allowed, and other sanitary advantages, its death-rate is far higher than that of the province of Bengal as a whole. The death-rate recorded for Bengal for the year under review was 31·04 against 38·2 for Calcutta; and this notwithstanding that the birth-rate recorded for the former was 38·57 as compared with only 10·7 in the latter.

3. To the death-rate of 38·2 for the year *plague* contributed 9·2 and *small-pox* 2·4. The number of deaths from plague shows a slight decrease as compared with that of the previous year, having been only 7,883 in the year under report against 8,354 in 1900. The number of deaths from small-pox, on the other hand, rose from 1,010 in the previous year to 2,097, and was not exceeded in any year since 1895. The mortality from *cholera* and *fever* was, in the case of each of these diseases, less than that recorded in the previous year, and also less than the mean of the preceding decade. Any facts which might add to our knowledge of *enteric fever*, the most fatal of all the diseases to which European soldiers in India are subject, deserve to be recorded. During the year under review 23 deaths from this disease were registered in Calcutta; but unfortunately it is not stated whether all, or any, of these occurred amongst the native population. Many of the cases, it is added, were verified by Widal's agglutination test, but the specific bacillus was not found in the town water, and though sanitary defects were present in the surroundings of several of the cases, there was no sufficient evidence to establish with anything like certainty the source of the infection. The most remarkable point connected with this brief notice of the disease is the smallness of the number of deaths attributed to it in a total of 32,450 deaths from all causes and in a population exceeding three-quarters of a million.

4. Consequent upon the partition of the town into four districts, the Vaccination Department has been abolished. The old vaccinators have been replaced by Hospital Assistants working directly under the orders of the Health Officers. The numbers vaccinated during the year were the largest ever recorded except in 1895; and the percentage of successful cases in primary vaccination was 98·3. But it is too early to judge of the improvement in the work of vaccination which is expected to result from the changes mentioned. That there was room for improvement in the administration of the Vaccination Department may be deduced from an examination of Table No. XII., in the Appendix to the Report. After all, the ultimate test of the value of vaccination is its success in preventing small-pox Applying this test to Calcutta, it will be seen from the table referred to, that during the 16 years preceding 1895 the deaths from small-pox never reached a thousand in any one year, and that they were fewer than a hundred in nine of those 16 years, whereas during the past seven years the small-pox deaths recorded in one of them were more than a thousand, and in each of two others more than two thousand. Without attaching too much importance to such statistics, it is undeniable that in recent years Calcutta has suffered more severely from small-pox than during any period between the great epidemic of 1865 and the epidemic of 1895.

5. The Report bears testimony to increased energy on the part of the authorities in their endeavour to ameliorate the insanitary conditions acknowledged to be in large part responsible for the high death-rate of Calcutta. The difficult task of effectually draining the town is being worked out at immense cost; and the question of the best way of converting the present intermittent water-supply into a continuous supply is under consideration. Fortunately, so far as the quality of the filtered water supplied to the town is concerned, the Health Officer is able to report that this "compares very favourably with that of the largest towns of Europe." But "the lamentable state of the drainage in the suburban area, the unhealthiness of the locality and the high death-rate undeniably point to the urgent need for action." The presence of plague has directed increased attention to the need for demolishing insanitary dwellings and carrying out "bustee" improvements. The demolition of insanitary huts and the clearing, or opening out, of overcrowded areas lead, however, to other difficulties. The displaced inhabitants of these huts and areas have to be compensated for disturbance and provided with suitable dwellings elsewhere. None too soon, intramural burials have been prohibited in the interest of the public health, and a number of cemeteries and burial grounds closed by the order of Government. Altogether, it is evident that a determined effort is being made to grapple with the insanitary conditions to which the high death-rate of Calcutta is known to be in great part due.

No. 14.

Memorandum by the Army Sanitary Commission on the Administration Report of the Madras Municipality for 1901–02.

The calendar year 1901 was, throughout, a very unhealthy one. Except in December, the temperature was above the average during every month, and the rainfall exceeded the average by 10·82 inches. Humidity was above the average in all of the months except March, May, and June. In conjunction with other conditions unfavourable to health, the dearness of the staple food (grains) it is said "tended to affect the vitality of the poorer classes, and to lessen their power of resistance to disease."

2. The *birth-rate* fell from 40·5 in the previous year to 37·0. These rates are calculated in the case of both years on the new census figures of 1901. The birth-rate of the previous year, calculated on the census figures of 1891, was 45·6, another illustration of the wide divergence in the ratios of vital statistics which may result from continuing to calculate them on the population numbers of the previous census instead of on the population as altered by natural increase, immigration, emigration, &c., in the course of the succeeding years. And yet this error would not have been got rid of by using the population numbers estimated by annually adding to or subtracting from them the excess or deficit of births as compared with deaths, or by assuming that the increase or decrease would proceed at the same rate as during the preceding intercensal ten years. Had the former of these two methods been used for calculating the population of Madras city for 1900, the result would have been that the figures of the census of 1891 would have shown a reduction of 4,409, the births registered since last census having been fewer than the deaths registered during the same period by that number. But the numbering of the people showed that not only was there no such decrease, but that the population of 1900 exceeded the population of 1891 by 56,879 persons. Had the latter, and ordinary, one of the two methods of estimating the population been adopted a nearer approximation to its actual number would have been attained, the increase between the taking of the census of 1881 and that of 1891 having amounted to 46,670 as compared with 56,879 between the census of 1891 and that just taken.

3. The *death-rate*, calculated, as in the case of the birth-rate, on the census population numbers of 1901, rose to 55·0 from 41·1 similarly calculated for the preceding year. The census numbers for 1891 having been used in calculating ratios in 1900, the death-rate recorded in the report for the latter year was 46·2. The explanation given of the difference between the birth-rate recorded for 1900 in the report for that year and its birth-rate calculated in the present report for comparison with the rate for 1901 applies equally to its death-rate. The increased death-rate for the year under report was due to greater mortality from all the chief diseases except measles.

4. *Cholera* was present in the city during every month of the year, and was simultaneously prevalent in the surrounding villages. Quoting from the report :—" It has always been a discussion whether these villages were the means of introducing cholera into the city or *vice versa*." Probably the same cause, or causes, which were accountable for the development and propagation of the disease in the city co existed and produced similar results in the surrounding country. This has been remarked with regard to other diseases. During years of unusual fever prevalence in towns, such, for example, as Calcutta, it has frequently been observed that the surrounding country suffers simultaneously, and to nearly the same degree. Except that it was more severe, the cholera epidemic of the year under report " ran identically the same course almost in every detail " as in 1900. In both years the greatest number of attacks occurred at exactly the same period of the year almost to a day, namely, from the 16th of August to the 26th of September. This coincidence, it is observed, " more than ever proves the close relationship the epidemic bears to seasonal influences." There seems to be no doubt that the mortality caused by cholera in the city was much greater than the returns would indicate. As always happens in India, when those discovered to be suffering from the disease are removed from their homes to hospitals, much concealment of cases follows to avoid such removal, and the disinfection of the houses in which attacks have occurred. To such an extent has this concealment of cases of cholera been carried in many towns that it has been found expedient not to insist on the removal of the sick from their houses to isolation hospitals, but to treat them as far as practicable in their own homes. Unsatisfactory as the latter method of dealing with those suffering from cholera must necessarily be, it may be a question whether it is not preferable to the forcible removal of the sick to hospitals when such action has the effect of arousing the opposition of the people, who, by a system of passive resistance and concealment of the sick, are able to defeat the best efforts of the authorities to arrest the progress of the epidemic by isolating the infected from the healthy. Regarding the effect produced on the epidemic by well-disinfection, the following remark is made :—" As a preventive measure early in the outbreak wholesale hankinization of wells in certain localities was tried without any great obvious benefit." This experience coincides with that recorded by the Inspector-General of Prisons, United Provinces, in his Report for 1901.

5. *Small-pox* was accountable for 292 deaths, or a ratio of 0·5, per thousand of population. This, although the highest ratio recorded in the decennium, cannot be regarded as excessive. Vaccination, as shown by its history during the present and past years, is efficiently carried out, and to this the city of Madras doubtless owes the comparative lowness of its mortality from small-pox during a year of epidemic prevalence of the disease. The bye-laws relating to vaccination are not here allowed to become a dead letter, as they are in some places. No fewer than 821 prosecutions took place in consequence of neglect to obtain vaccination. In 618 of these cases vaccination was effected, whilst in the other remaining cases the majority had left the town, or vaccination had to be postponed on account of illness. In paragraph 132 the percentage of success is calculated on the combined results in primary vaccination and re-vaccination. But, as the better the quality of primary vaccination the lower will be the percentage of success in re-vaccination, the paradoxical result follows that the percentage of success will be lower in the combined result in proportion as the quality of the primary vaccination is higher. In Statement No. I, Appendix IV, the percentage of success is shown separately for primary vaccination and re-vaccination ; in the former this is recorded to be 98·96, and in the latter 70·59. By far the greater number of cases were vaccinated direct from calf to arm. In those cases the percentage of successful operations recorded was 89·34. The highest percentage of success followed the use of glycerinated lymph, and the lowest, 72·88, resulted from vaccination with lanoline lymph. Hitherto calf-to-arm vaccination has usually given better results than vaccination with glycerinated lymph.

6. The mortality from *fever* was the highest ever recorded in the city, and is said to have been " largely determined by the insanitary conditions which obtain in Madras, viz., over-crowded and ill-drained houses in undrained areas, with an insufficiency of food."

7. The "passport system," vigilantly carried out, has been attended with remarkable success in excluding *plague* from Madras. Whilst the other Presidency cities and many of the large towns throughout India have been severely visited by plague, Madras has hitherto enjoyed almost complete immunity. During the year under report no indigenous case occurred although five cases were imported, two of which proved fatal.

8. In former reports the chief sanitary wants of Madras city have been stated to be the completion of its drainage system, and the improvement of its water supply. To these should be added the opening out of the "congested and foul *parcheries* of Black Town and other densely populated quarters." The completion of the drainage works is to take precedence of the improvement of the water supply. Regarding the quality of the water during the year under report, it is stated that the Chemical Examiner found it to be satisfactory except during the four months July—October, when it was reported to be "suspicious." Reference to the returns of cholera shows that during three of those four months the disease was most prevalent and fatal. The excessive sickness and mortality of the year under report, due in great part, as they are acknowledged to have been, to well-known insanitary conditions, will doubtless stimulate the municipal authorities to increased effort to hasten the removal of those conditions

---

No. 15.

MEMORANDUM by the ARMY SANITARY COMMISSION on the ADMINISTRATION REPORT of the MUNICIPAL COMMISSIONER of the CITY of BOMBAY for the year 1901–02.

The Annual Report of the Executive Health Officer is written by Dr. J. A. Turner, who was in charge throughout the year. The report is brief, but comprehensive. Following it is a short account of the working of the Municipal Hospital for Infectious Diseases at Arthur Road, by the Special Assistant Health Officer, Dr. Chosky. The latter, in addition to his other work, undertook, but has not yet completed, an inquiry into the character and type of the relapsing fever which has been prevalent in Bombay for several years past.

2. The mortality, which had steadily grown since the plague first appeared towards the end of 1896, at length showed a decided decrease in the year under report. This decrease was not due to any decline in the prevalence of plague, for this, on the contrary, was more fatal than in the previous year, but to an abatement in the severity of the cholera, small-pox and measles epidemics, from which the city suffered in the preceding year.

3. The improved system of registration of *births* and *deaths* introduced by the new Executive Health Officer has not yet had sufficient time to produce any very marked effect on the birth and death rates. The number of births registered was, however, greater than in the previous year by 832, the birth-rate rising to 17·42 from 15·43 in that year. The lowness of the birth-rate is undoubtedly in large part due to the disproportion in the numbers of the sexes in the City of Bombay ; there being to every 100 females 161·96 males. The improved system of registration has, so far, failed to show that there has hitherto been exaggeration in the recorded number of still-births. Last year the number of these registered was 2,062 ; and this year the number has risen to 2,153 against 13,520 children born alive. This abnormally high proportion of still to live births has always been a feature of the vital statistics of Bombay, and still awaits a satisfactory explanation.

4. The *death-rate* which had risen in 1900 to 96·56 per thousand of population, fell in the year under report to 76·66 ; but was still above the average for the past five years. The mortality amongst the infant population, usually regarded as a reliable measure of the healthiness or unhealthiness of a locality, was enormous. Whilst the number of live-births registered during 1901 was 13,520, the number of children who died within their first year of life was 7,768 or 574·5 per thousand.

5. Chief among the causes of death was *plague*, which of itself accounted for a death-rate of 24·14 out of a total from all causes of 76·66. The disease was of a very virulent type, the mortality in hospitals varying from 79 to 91 per cent. The Health Officer has little that is new to say regarding it. The experience, he says, gained during the past years in its prevention and treatment shows that overcrowding, poverty and insanitary conditions contribute to its spread ; whilst nothing can be more evident than that fresh air, sunlight, and improved sanitary surroundings have an opposite effect. Experience and observation of these facts seem to be, at length, convincing the inhabitants that their best hope of safety lies in the evacuation of their crowded and insanitary dwellings and movement into camp. It is stated that 13,000 persons were received in the municipal camps during the plague epidemic of 1901, and that the percentage of deaths in these camps was only 0·56. Besides these, about 25,000 people removed of their own accord into the private camps on the sea-face and in the north of the island. It would thus appear that the plague-stricken inhabitants of the cities of the plains are tardily realising the value of the method of dealing with plague which has long been successfully practised by villagers in the Himalayas. From such voluntary action on the part of the people themselves more is to be hoped than from all the elaborate and costly measures which the State can bring into operation in the endeavour to circumscribe or stamp out the disease amongst a population so numerous, so ignorant and superstitious as that of India.

6. The decline in the mortality from *cholera, small-pox*, and *measles* was marked. Together, these diseases accounted for 8,791 deaths in the previous year, and in the year under report for only 424. A table is inserted in the Health Officer's report recording, but without comment, the results of the season's vaccination operations. From this table it appears that, of a total of 12,945 primary vaccine operations which were successful, 11,202 were performed on children under one year of age. Seeing that, as already noted, only 13,520 live births were registered during 1901, and that 7,768 children died within their first year, it is evident that few, if any, of those born in the city could have escaped vaccination. But in Bombay the exogenous element so largely preponderates in the population that no certain deduction can be drawn from these figures. If the number of people who were not born in, but had immigrated into, the City of Bombay may be estimated from the number of deaths of persons who died there but were born elsewhere, the indigenous element forms but a comparatively small proportion of the total population. According to the statement in paragraph 29 of the Health Officer's report, of a total of 59,495 persons whose deaths were registered in the city during the year, only 13,064, or less than one fourth, were born there. From which it may be assumed that Bombay city depends more upon immigration than upon reproduction within itself for the recruitment and maintenance of its population numbers.

7. *Phthisis and respiratory diseases* had, as usual, a large share in the causation of the mortality for the year. Under these headings no fewer than 14,320 deaths were registered, giving a death-rate per *mille* of population of 18·44. The causes of the enormous mortality from phthisis in Bombay city are well known. Although females are in the proportion of only 100 to 161·96 males in the population, the deaths from phthisis among the former numbered 3,355 as compared with 3,161 among the latter. The remarkable differences in the incidence of this disease in the different sections of the city are well shown in the statements on page 159, and may be taken as some measure of the comparative unhealthiness of the several sections

8. A total of 7,921 deaths was registered from *fevers* of all kinds. Of this number over seven thousand were ascribed to the remittent type ; but, as the Health Officer observes, a careful diagnosis might have ascertained that many of these were due to relapsing fever or to plague. An examination of the returns month by month shows that the fever mortality rose and fell with the mortality from plague. It is interesting to note that of the total number of deaths attributed to fevers of all types, only 62 were ascribed to enteric fever. Unfortunately, the number of these cases which occurred amongst Europeans and Eurasians and the number among natives are not separately stated ; but assuming that all of them occurred amongst the seven hundred thousand natives of Bombay—and this unlikely—it is another proof of the comparative immunity from this type of fever enjoyed by the latter. Dr. Chosky, in his remarks on relapsing fever, notices the frequent concurrence of this disease with phthisis. This concurrence he found to much enhance its fatality ; when uncomplicated, the mortality from relapsing fever, so far as his investigations have yet gone, is, he says, "comparatively low."

9. A description is given of the more serious of the defects inherent in the site of the city. To these are due in a large measure the difficulties encountered in devising and carrying out an efficient system of drainage. But, "until a complete system for the removal and disposal of sewage and storm-water has been provided which will at once remove all sewage matter out of the city, any improvement in public health will necessarily be slow." Of hardly less importance than drainage is the proper housing of the working classes. "Much has been written about the conditions under which these poor people live—the overcrowding, poverty, and filthy surroundings, the dark, damp, ill-ventilated rooms have been commented on in many previous reports—but little has actually been done to relieve them." The influence of such conditions in accentuating the prevalence of plague is manifest in the cold weather when the people are obliged to sleep indoors.

A. GODLEY,
Under Secretary of State for India.

INDIA OFFICE,
October, 1904.

REPORT.

The present Report on Sanitary Measures in India during the year 1902 is prepared for presentation to Parliament. It contains chapters on the health of the European and Native troops, on the health of prisoners in jails, and on the health of the general population ; it also contains chapters on vaccination, on medical institutions, including medical schools and lunatic asylums, and a chapter on sanitary works. Appended to the Report are abstracts of reports by the three principal Sanitary Commissioners in India, and memoranda by the Army Sanitary Commission in England reviewing the several Sanitary Reports for India.

I.—EUROPEAN ARMY.

Sickness and mortality in 1902.

The health of the European troops serving in India during the year 1902 was on the whole satisfactory ; the admission, daily sick and invaliding rates were slightly lower but the death-rate was higher. On an average strength of 60,540, the admissions into hospital were in the ratio of 1,078 per 1,000, against 1,104 in 1901, the daily sick-rate fell from 67 to 66, and the death-rate rose from 12·38 to 14·68. The invaliding ratio (37) was lower by 2 per 1,000, so that the total loss by death and invaliding was equal to 52 per 1,000, an increase of 1 per 1,000 on the previous year.

The following statement shows the relative extent of sickness and mortality among European troops in the four Commands during 1902 and the previous year :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.				
			Admissions.	Daily Sick.	Deaths.	Invaliding.	Total Loss.
Bengal	1901	19,000	980	62	12·95	37	50
	1902	17,765	1,063	71	15·31	36	51
Punjab	1901	16,431	1,090	63	12·90	38	51
	1902	15,036	1,050	62	14·07	35	49
Madras	1901	10,282	1,278	79	9·34	43	52
	1902	11,097	1,083	70	8·92	40	49
Bombay ...	1901	15,125	1,140	69	13·16	42	55
	1902	14,404	1,125	67	19·58	43	63
INDIA ...	1901	60,838	1,104	67	12·38	39	51
	1902	60,540	1,078	66	14·68	37	52

It will be seen from the above statement that Bombay was the most unhealthy of the four Commands, Bengal coming next, and both were more unhealthy than in the previous year. In regard to mortality, there was an improvement only in Madras, where the death-rate fell from 9·34 to 8·92.

The chief causes of sickness in the whole European Army were, as usual, ague and venereal diseases, the former yielding a ratio of 281 per 1,000 against 276 in 1901, and the latter 247 per 1,000 against 293. Forty-nine per cent. of the total sickness resulted from these two causes. Enteric fever, as usual, was the chief cause of mortality, the death-rate from it being 4·29, or nearly 1 per 1,000 higher than the ratio of the previous year. Twenty-nine per cent. of the total deaths were due to this cause.

Groups of stations.—The following table shows the sickness and mortality among the European troops according to groups :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,044	1,147	66	12·45
Burma Inland	1,631	1,426	91	11·65
Bengal and Orissa	1,809	1,234	70	24·32
Gangetic Plain and Chutia-Nagpur	5,454	1,076	75	14·30
Upper Sub-Himalayan	11,281	1,086	71	15·87
North-Western Frontier, Indus Valley, and North-Western Rajputana.	4,260	1,150	59	14·08
South-Eastern Rajputana, Central India, and Gujarat.	4,320	1,340	81	17·59
Deccan	8,594	1,144	71	13·73
Western Coast	1,593	742	56	21·34
Southern India	3,495	954	53	6·87
Hill Stations	8,324	873	57	13·33
Hill Convalescent Depôts and Sanitaria ...	3,229	1,152	76	18·27

Of the above 12 groups, seven returned a higher daily sick-rate than that for the European Army as a whole, and in five groups the death-rate was greater. The most unhealthy groups, judged by the daily sick-rate, were Burma Inland and Central India, with daily sick-rates of 91 and 81 per 1,000 respectively.

Of the stations with a strength of over 1,000, the highest death-rates were those of Colaba (24·96), Karachi (21·0), Quetta (19·26), Rawalpindi (18·93), Mhow (17·89), Umballa (17·27), Poona (16·50), Meerut (15·95), Sialkot (15·10), and Agra (14·72).

Cholera.—There was again very little cholera among the European troops, only 3 cases having been recorded during the year, against 12 cases in 1901. In both years all the cases were fatal.

Small-pox.—Among the whole of the European troops in India there were during the year under notice 23 cases of small-pox with four deaths. In the previous year there were 20 cases and three deaths.

Fevers.—From intermittent fever the admission-rate per 1,000 among the European troops was less than in 1901, viz., 247 against 293, but the death-rate rose from 0·36 in 1901 to 0·50 per 1,000.

Enteric fever was more prevalent than in the previous year. The admissions rose from 776 or 12·8 per 1,000 of strength to 1,012 or 16·7, and the deaths from 202 or 3·32 per 1,000 to 260 or 4·29. Of the four Commands Bombay recorded the highest mortality under this head, viz., 5·69, followed by the Punjab 5·05, Bengal 4·00, and Madras 1·71. Among the larger stations with an average strength of over 1,000, Sialkot returned a death-rate from this fever of 8·88, Meerut 8·70, Quetta 7·71, Mhow 7·53, Umballa 7·06, Lucknow 6·22, Colaba 6·05, Poona 5·85, Peshawar 5·54, and Rawalpindi 4·63. As usual, young and unacclimatised soldiers were the chief sufferers; among those from 20 to 25 years of age the death-rate was 7·06 per 1,000 against 4·91 in 1901, while among men between 25 and 30, and from 30 to 35 the mortality was 2·91 and 1·92 per 1,000 respectively. Among men of less than one year's residence in India the death-rate from this fever was 13·50 per 1,000, among men between one and two years 4·61, and among men between five and ten years' service 2·74 per 1,000. Of the total 260 deaths from enteric fever, nearly 60 per cent. occurred among men between the ages of 20–25, and 27 per cent. among men between the ages of 25–30.

Bowel Complaints.—The admissions from dysentery and diarrhœa among the European troops were in the ratio of 33 per 1,000 of strength, or 2 per 1,000 less than in 1901. The mortality from dysentery was in the ratio of 0·69 against 0·97 in the previous year, and from diarrhœa 0·05 against 0·02. Dysentery was most prevalent, as usual, in the Bengal-Orissa group, and as regards the Commands it was more prevalent and fatal among troops in the Bengal Command.

Abscess of the Liver.—From abscess of the liver there were 112 deaths, giving a ratio of 1·85 per 1,000 of strength, against 101 or 1·36 in 1901.

Plague.—There were only four cases of plague among the European troops, and one death, against three cases and one death in 1901.

Venereal Diseases.—Venereal diseases ranked first in the list of causes of admission to hospital, and first in the causes of invaliding. They were the cause of 26 per cent. of the total sickness during 1902, and of 13½ per cent. of the invaliding of the European Army of India. The admission-rate from venereal diseases per 1,000 of strength was 281·4, being 5·4 higher than in 1901, thus interrupting the steady yearly decrease which commenced with the year 1896. The slight increase is attributed chiefly to the arrival of a number of regiments or drafts of regiments from field service in South Africa. Of the four Commands, Madras returned the highest ratio, viz., 343·4 against 354·4 in 1901; Bengal followed with 299·4, against 258·8; Bombay 286·7, against 282·6; and the Punjab 217·5, against 229·1. The number of men constantly sick in hospital from these diseases was 1,431, against 1,416 in the previous year; and the average stay of a case in hospital was about 31 days. The deaths from these diseases numbered 15, and the invalidings 310, against 8 and 383 respectively in 1901.

Invaliding.—The loss to the whole European army by invaliding during 1902 amounted to 2,255 men, equal to 37·25 per 1,000 of strength, against 2,393 or 39·33 in 1901. The proportion of invalids to strength was highest in the Bombay Command (42·70), followed by Madras (40·37), Bengal (35·86), and the Punjab (35·50). As regards the influence of age and length of residence in India upon invaliding, 35 per cent. of the total number invalided were under 25 years of age, against 42 per cent. in 1901, while 17 per cent. against 14 were of less than two years' service, and 48 per cent. against 60 were of less than five years' service.

II.—NATIVE ARMY.

Sickness and Mortality in 1902.—The health of the Native Army of India was on the whole better than in 1901, though the death-rate was slightly higher.

The ratios of sickness and mortality among Native troops in the five Commands during 1902 and the previous year are given in the following table :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.		
			Admissions.	Daily Sick.	Deaths.
Bengal	1901	26,200	667	27	8·44
	1902	26,652	629	25	8·03
Punjab	1901	46,050	944	30	12·03
	1902	43,486	746	27	12·76
Madras	1901	18,622	699	28	8·80
	1902	18,017	704	28	12·77
Bombay	1901	22,428	933	35	12·93
	1902	24,371	856	30	11·65
Hyderabad Contingent	1901	5,826	543	21	4·81
	1902	6,204	518	18	9·83
INDIA	1901	122,806	829	30	10·68
	1902	124,231	718	27	11·16

Of the five Commands, Bombay was again the most unhealthy in 1902, though its death-rate of 11·65 per 1,000 was exceeded by those of the Punjab and Madras Commands. Pneumonia continued very prevalent in the Punjab and Bombay Commands, and the death-rates from it were 5·70 and 4·39 per 1,000 respectively.

The chief cause of sickness in the Native Army was ague, which contributed 38 per cent. of the total admissions. Among the diseases from which the admissions to hospital were higher than in 1901 were small-pox, enteric fever, tubercle of the lungs and pneumonia ; while from influenza, cholera, respiratory diseases other than pneumonia, diarrhœa, and venereal disease there was a decrease in the admissions. From cholera the admission-rate fell from 0·3 per 1,000 of average strength in 1901 to 0·2, and from venereal diseases from 34·3 to 32·8, as compared with 281·4 per 1,000 among European troops. There were 9 deaths and 121 invalidings from venereal disease, against 15 deaths and 310 invalidings among European troops.

Pneumonia was as usual the chief cause of death in the Native Army, and contributed 33 per cent. of the total deaths, the death-rate being 3·71 per 1,000 of average strength, against 2·72 in 1901. From this disease the mortality among the Native soldiers was nearly four times as great as that among European troops (0·97 per 1,000). Fevers of all kinds were the cause of 17 per cent. of the total deaths, against 34 per cent. among the European troops. From ague, remittent and simple continued fevers, the deaths among the Native troops were in the ratio of 2·06 per 1,000, while among the European troops the proportion was 0·70. On the other hand, the death-rate from enteric fever among the Native troops was only 0·10 per 1,000, as compared with 4·29 among the European troops.

From cholera there were only 15 deaths in the Native Army, equal to 0·12 per 1,000 of strength, as compared with 19 or 0·15 in 1901.

During 1902 there were 192 cases of plague among the Native troops with 95 deaths, against 70 cases and 41 deaths in 1901.

Groups of stations.—The following statement gives the principal statistics of the Native Army, arranged in geographical groups, for 1902 :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,362	1,043	26	5·14
Burma, Inland	3,659	983	33	6·56
Assam	1,427	651	32	8·41
Bengal and Orissa	2,280	824	34	8·33
Gangetic Plain and Chutia-Nagpur	6,136	516	21	8·15
Upper Sub-Himalayan	14,978	636	23	9·15
North-Western Frontier, Indus Valley, and North-Western Rajputana.	16,472	901	32	12·81
South-Eastern Rajputana, Central India, and Gujarat.	10,754	898	33	12·55
Deccan	15,978	631	24	8·64
Western Coast	1,670	701	27	11·38
Southern India	6,270	728	32	22·33
Hill Stations	20,950	822	32	13·70

In seven of the 12 groups the daily sick-rate was higher than that for the whole Native Army, and in five the mortality was greater. The highest mortality was recorded by the Southern India group, viz., 22·33, of which pneumonia contributed 4·31. In 1901 this group returned a death-rate of 10·25.

Of the large stations with a strength of over 1,000, the following recorded the highest death-rates :—Bangalore 33·77, Dera Ismail Khan 23·65, Aurangabad 21·86, Meean Meer 20·27, Abbottabad 16·20, Ferozepore 14·42, and Quetta 12·37, in all of which, except Abbottabad and Quetta, pneumonia was the chief cause of death.

III.—GENERAL POPULATION.

The year 1902 was comparatively dry, the rainfall in India as a whole having been slightly below the annual mean.

Registration of vital statistics in the British provinces of India though improving is still very imperfect and defective, and the statistics must still be regarded as possessing only comparative value. In 1902 the birth-rates of the several provinces varied between 56·9 per 1,000 of population in Berar and 23·91 in Coorg, and the death-rates between 44·11 in the Punjab and 20·20 in Madras Presidency. Of the chief diseases cholera was less prevalent and the deaths fell from 271,210 in 1901 to 224,135. The North-West Frontier Province and Coorg were quite free from the disease, and in all the other provinces, except Bengal and Assam, the mortality was lower than in the previous year. The mortality from small-pox continued to rise, and accounted for 115,603 deaths, being an increase of 25,818 on the number recorded in 1901. From fevers also the number of deaths was somewhat larger than in the previous year, aggregating 4,291,952 or 60·5 per cent. of the total deaths. Deaths from dysentery and diarrhœa fell slightly from 248,287 to 236,869. Plague spread considerably during the year, and the deaths rose to 445,293, an increase of nearly 90 per cent. on the mortality in 1901. Of these 184,752 occurred in Bombay, the Punjab coming next with 171,302, followed by the United Provinces and Bengal with 40,223 and 32,967 deaths respectively.

The deaths from the chief diseases and from all causes in the several provinces were as follows :—

Provinces.	Cholera.		Small-pox.		Fevers.		Dysentery and Diarrhœa.		Plague.		Deaths from all causes.		
	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000. 1902.	Ratio per 1,000. 1901.

Bengal.

In Bengal the health of the general population in the year 1902 was not good. The birth-rate rose from 38·57 per 1,000 of population in 1901 to 40·14, which was made up of district ratios ranging from 53·10 in Noakhali to 9·08 in the Sonthal Parganas. In 25 other districts the birth-rate exceeded 40 per 1,000. There was an increase of 178,004 deaths during the year, the number having risen from 2,310,424 to 2,488,428, and the death-rate from 31·04 to 33·43. The rise in mortality was chiefly due to the greater prevalence of fever and cholera, and to the fact that infantile mortality was much higher than in the preceding year. The highest district death-rate was 51·28 in Nadia, and in 18 other districts the provincial rate was exceeded.

Of the chief diseases cholera prevailed with greater severity than in the previous year and claimed 150,971 victims, or 2·02 per 1,000, against 110,753 or 1·48. No

district was absolutely free from the disease, and it prevailed in 11 per cent. of the villages against 9·3 per cent. As measures of prevention the disinfection of wells with permanganate of potash was carried on in 20 districts, and is said to have been attended with beneficial results. The results of anti-cholera inoculation were satisfactory. Out of 106 inoculated coolies on board the steamer going from Goalanda to Dibrugarh there was only one case of cholera, which recovered; while out of 1,192 uninoculated coolies 18, or 1·51 per cent. were attacked, and four died.

The mortality from small-pox again rose from 37,680 or 0·50 per 1,000 of population to 57,430 or 0·77. The disease was present in all the districts, but it prevailed with the greatest intensity in Midnapore, Singhbhum, and Patna, which recorded death-rates of 6·39, 5·36, and 3·05 per 1,000 respectively, against 2·49, 1·32, and 0·51 during the preceding year. In the first and second of these three districts the epidemic apparently survived from the previous year, when the mortality was unusually high. On the whole the incidence of the disease was higher in 24 districts, lower in 21, and equal to that of the preceding year in one district. Out of the total small-pox deaths over 57 per cent. occurred amongst children under ten years of age.

About 69 per cent. of the total mortality was recorded under fever, the deaths numbering 1,721,921, or 23·13 per 1,000, being the highest ratio recorded since 1897. As regards the relative intensity of fever in each district, Nadia recorded the highest death-rate of 40·86 per 1,000, against 26·95 in the preceding year, and in eight other districts the death-rate was over 30 per 1,000 of their respective populations. In consequence of the greater prevalence of fever during the year there was a considerable increase in the demand for quinine, no less than 34,114 parcels of the drug (each parcel containing 102 five-grain pice packets) having been sold, against 30,593 parcels in 1901.

Deaths from dysentery and diarrhœa fell from 59,643 or 1·80 per 1,000, to 56,995 or 0·76. As compared with the previous year the incidence of these diseases was higher in 24 out of the 46 districts in the province. The mortality in towns was five times greater than in rural areas. "This," the Sanitary Commissioner remarks, "must continue to be so on account of the overcrowding and its attendant evils being more pronounced in towns than in the open country, and of the greater probability of the disease being correctly diagnosed and reported in the former."

Plague was present in the province throughout the year. It prevailed, however, with much less severity than in 1901, the mortality from it amounting to 32,967 or 0·44 per 1,000, against 78,629 or 1·05. Calcutta was the chief sufferer, with a death-rate from the disease of 8·58 per 1,000 of population, followed by Saran with a ratio of 5·68; Patna, which recorded a mortality of 16·86 in 1901, coming third with a ratio of 1·71. The same preventive measures continued in operation, viz., (1) disinfection; (2) evacuation of infected houses and localities; and (3) anti-plague inoculation; but the second measure was the only one in favour with the people. Inoculation was resorted to in three districts, but only a small number of operations was performed, the feeling of the people being against this form of protection.

The Municipality of Calcutta recorded a birth-rate of 14·2 and a death-rate of 37·0 per 1,000 of population. The high death-rate was attributed to the recurring epidemic of plague in the first half of the year. Excluding this factor the ratio is reduced to 28·4, which is only slightly above the mean of the decade (27·4). Cholera accounted for a larger number of deaths than usual, but the mortality from small-pox was comparatively low again after two bad years, and the deaths registered under fever were much below the mean. An important reform was introduced during the year, under which all cases of death that occur are inquired into by Sanitary Inspectors, nearly all of whom are qualified medical men. One result has been the detection of a considerable increase in the mortality from tuberculosis. The Health Officer attributes fully 10 per cent. of the total mortality of the city to this disease.

United Provinces of Agra and Oudh.

The health of the United Provinces of Agra and Oudh in 1902 was fairly satisfactory. Both birth and death rates were above the normal; but while the excess was slight as regards deaths it was very marked as regards births. The birth-rate was 45·84 per 1,000, being second highest among the provinces of India, and exceeded the death-rate by 13·30 per 1,000. All the districts except Naini Tal and Cawnpore returned birth-rates in excess of death-rates. The number of deaths recorded rose from 1,445,035 or 30·30 per 1,000 in 1901 to 1,552,046 or 32·54, which was composed of extremes varying from 49·50 in Cawnpore to 23·80 in Azamgarh. The high mortality in Cawnpore was due chiefly to a severe outbreak of plague, resulting in 9,753 deaths, or 7·75 per 1,000 of its population.

Cholera showed a further abatement in severity. The number of deaths from it (25,160) was less than a half of that (53,995) recorded in the previous year. The resulting death-rate was 0·53 per 1,000, which was exceeded in 19 districts, the highest being 2·32 in Banda. In five other districts the ratio was over one per 1,000.

Small-pox was considerably more fatal than in 1901, and visited every district except Garhwal and Mainpuri. Of the 4,976 deaths, all but 497 occurred among children under ten years of age.

Fevers contributed nearly three-fourths of the total mortality, the death-rate under this head being 24·51 per 1,000, against 23·46 in the previous year.

The mortality from dysentery and diarrhœa was much about the same as in the previous year, and the death-rate of 0·58 per 1,000 was made up of district ratios ranging from 8·13 in Garhwal to 0·02 in Bahraich and Kheri.

Plague largely increased during the year, and deaths to the number of 40,223 were recorded. These occurred in 34 of the 48 districts ; but in 14 the number was very small and the cases were almost all imported. The mortality was much higher among females than males, and this, the Sanitary Commissioner states, "may very possibly be due to the facts that native females spend far more time inside their houses and courtyards than men, and moreover, do not so habitually use shoes."

Punjab.

In the Punjab the recorded birth-rate rose from 35·4 per 1,000 of population in the previous year to 43·8, which is the third highest in the list of the provinces of India. In every district there was an increase, and in 11 out of the 27 districts the rise exceeded the provincial increase of 8·4 per 1,000. The death-rate of the province was 44·1 per 1,000, being higher than that recorded in any other province, and higher than the birth-rate by 0·3. The total registered mortality was 886,973, against 726,611 or 36·1 in 1901. The increase of eight per 1,000 in the death-rate was almost entirely due to plague, which prevailed with extreme virulence in the districts of Ludhiana, Sialkot, Umballa, Jullundur, Gurdaspur, Lahore, and Hoshiarpur, and accounted for their abnormally high death-rates, ranging from 103·9 to 41·7 per 1,000.

The province was again almost free from cholera, only 371 deaths being registered, against 180 in 1901. The disease was chiefly confined to the Delhi division, four districts of which returned 321 of the total deaths. An isolated outbreak occurred in a village in the Kangra district, Jullundur division. There were 65 seizures and 38 deaths, all of which occurred in one week. The origin of the outbreak is reported to have been due to the contamination of the drinking water of one of the village tanks by the washing of the soiled linen of a sepoy who had returned to the village from Burma suffering from diarrhœa on the way. On the inhabitants ceasing to use the water the tank was disinfected by permanganate of potassium, and "the cases ceased immediately."

Small-pox was much more prevalent than in the previous year, and the death-rate rose from 0·31 to 0·58 per 1,000. More than three-fourths of the total 11,629 deaths occurred amongst children under ten years of age. The disease was present in all the districts, but only in Montgomery did the death-rate exceed one per 1,000. Several of the towns in which vaccination is not compulsory suffered very severely, 10 recording death rates ranging from 11·83 to 5·12 per 1,000 ; while of the 22 towns in which the Vaccination Act is in force the highest recorded ratio was 1·6 per 1,000.

Deaths ascribed to fever fell from 508,035 or 25·3 per 1,000, to 473,352 or 23·54. The most striking feature of the returns for 1902 was the great prevalence of fevers in five out of the seven districts of the Delhi division, in which the fever death-rate ranged between 29·72 and 33·46 per 1,000, these being the highest district rates recorded during the year. In several districts the mortality under this head showed a remarkable decrease, notably in Ludhiana and Ferozepore, where the death-rates were less by 17 and 13 per 1,000 respectively.

The mortality from dysentery and diarrhœa was slightly less than in 1901, and the death-rate, 0·70 per 1,000, was exceeded only in nine districts, the highest being 1·57 in Simla and 1·49 in Gurdaspur.

Plague was very prevalent in the Province during the year, and the deaths rose from 14,959 to 171,302, giving a death-rate of 8·52 per 1,000. The epidemic was at its height in March and April, when 100,912 deaths, or three-fifths of the entire plague mortality, was recorded. The disease was chiefly confined to the central and thickly inhabited portion of the province, the greatest sufferer being the district of Ludhiana which lost during the year 71 per 1,000 of its population from plague. The ravages committed by the disease in some of the minor towns and villages in this district were terrible. In all the infected districts the epidemic with slight variations ran the same

course, increasing rapidly in the winter months, reaching its elimax in spring, and declining suddenly with the commencement of the hot weather.

North-West Frontier Province.

In the North-West Frontier Province the birth-rate was 33·6 per 1,000 of population, showing an increase of 4·1 as compared with 1901 ; but compared with other provinces the rate was the lowest with the exception of Madras, which it exceeded by 5·4 per 1,000. The excess of births over deaths was 9·2 per 1,000, and in no district did the death-rate exceed the birth-rate. The death-rate was 24·4, being 5·3 higher than in the preceding year. The increase was almost entirely due to fever from which there were more cases in all the districts, especially in Kohat and Bannu, the rate of mortality under this head being 18·92, against 14·62 in 1901. Over 77 per cent. of the total deaths were ascribed to fevers.

Cholera was entirely absent from the province during the year, and there were only four deaths registered under plague, all of which were imported from the Punjab. On the other hand the mortality from small-pox was slightly more fatal than in the previous year, the number of deaths having risen from 955 to 1,081. One-fourth of these occurred among infants under one year of age, and a little more than half among children over one and under ten years of age.

Central Provinces.

The year under report was a dry and healthy one in the Central Provinces, and there was no epidemic mortality except from small-pox in certain districts and some plague at the end of the year. The recorded birth-rate rose from 28·83 in 1901 to 48·29, which is the highest proportion of births to population since registration was begun, being mainly due to a return to normal conditions after a period of distress. All the districts registered a higher birth-rate than in the previous year, and in all the births exceeded the deaths, the excess for the province being 219,495 or 22·47 per 1,000. The mortality was rather higher than that recorded in 1901, the death-rate being 25·82 against 23·46. With the exception of four, all the districts returned a higher death-rate than in the previous year.

Cholera was again remarkably quiescent, only 28 deaths having been registered against 49 in 1901. Of the former, 26 were returned by Bilaspur, where the outbreak is supposed to have been due to importation by pilgrims returning from Puri.

Small-pox was accountable for 4,394 deaths or 0·45 per 1,000, a decrease of 1,687 on the previous year's mortality. The disease was less prevalent in all but six of the districts, and of those which returned a high death-rate Damoh came first with 1·86, but only in three other districts did the death-rate exceed 1 per 1,000. Seventy per cent. of the deaths occurred among children under ten years of age.

As usual fevers were the most fatal of all the diseases. More than half of the total mortality was registered under this head and the death-rate was slightly higher than in the previous year, viz., 14·52 against 14·28. All the districts except seven recorded a higher fever death-rate than in the previous year, but the increases were not considerable. The mortality due to dysentery and diarrhœa fell from 1·18 per 1,000 to 1·11. Half the districts recorded a higher mortality under this head than in the previous year, the increase in each case however was slight.

Plague was indigenous in the districts of Nimar, Burhanpur, Jubbulpore and Wardha, and the total mortality from it was 1,061. As in the previous year only two inspecting stations were in existence, viz., at Burhanpur and Wardha.

Burma.

Registration of vital statistics in Burma continues still to be limited almost entirely to Lower Burma, where a birth-rate of 31·57 per 1,000 of population was recorded, or 0·5 lower than that of 1901, the decrease to some extent being accounted for by lack of energy in the matter of inspection of registers. The births however exceeded the deaths by 10·4 per 1,000. From the 13 towns in Upper Burma in which births are registered a birth-rate of 38·07 was returned, against 37·66 in 1901.

The year 1902 was normally healthy. In Lower Burma the death-rate fell from 21·74 in 1901 to 21·16, a mortality which is considered too low, and can only be accepted as relatively correct for the sake of comparison. The district death-rate in Upper Burma was 17·30 per 1,000.

The province was much freer from cholera than in the previous year. In Lower Burma the deaths fell from 3,552 or 0·64 to 1,844 or 0·33 per 1,000, and in Upper Burma there were only 57 deaths from the disease. Four districts and 10 out of the 13 towns in Upper Burma returned no deaths from cholera.

Small-pox was also much less prevalent in Lower Burma, the deaths falling from 2,468 to 1,565. In Upper Burma the deaths numbered 350. Of the total deaths from this disease 47 per cent. were children under ten years of age.

The mortality from fevers in Lower Burma was slightly higher than that of the previous year, the death-rates being 8·86 and 8·65 respectively. In Upper Burma fevers were very prevalent, and 18,393 deaths were registered.

Dysentery and diarrhœa were less fatal in Lower Burma during the year, and the death-rate fell from 1·47 per 1,000 to 1·30. In Upper Burma the mortality under this head was 661.

The whole province again remained free from indigenous plague throughout the year, but three cases, imported from Calcutta, were detected at the port of Rangoon, one terminating fatally.

Assam.

In Assam the year 1902 was not quite so healthy as the preceding year. In the area under registration, with a population of 5¼ millions, the births represented a ratio of 34·21 per 1,000, against 33·98 in 1901. In the Surma Valley the birth-rate was 36·90 and in the Brahmaputra Valley 31·48. In both valleys there was an excess of births over deaths, that for the whole province amounting to 5·20 per 1,000. The mortality exceeded that of the previous year by over 6,000, and the death-rate rose from 27·85 to 29·01, which was made up of district ratios ranging from 35·72 in Darrang to 18·14 in Sibsagar.

Deaths from cholera showed an increase of over 5,000, the number having risen from 7,468 or 1·42 per 1000 to 12,658 or 2·40. The disease was very prevalent in the Surma Valley, the two districts of which (Cachar and Sylhet) contributed over 75 per cent. of the total cholera deaths. Sylhet district recorded 8,804 fatal cases against 2,805 in 1901.

Small-pox also showed an increased mortality of 3,400, which was chiefly due to several outbreaks in the districts of Cachar and Sylhet. In the former the mortality was more than 13 times as high as in last year, and twice as high in the latter, the increase being attributed to the dissemination of small-pox contagion by inoculators. Over 67 per cent. of the total 6,673 small-pox deaths occurred among children under ten years of age.

Although the rainfall was above the average in all districts except Lakhimpur, malaria was not nearly so prevalent as in the previous year, and there was a decrease in fever mortality. The death-rate from fevers, including *kala-azar* was 14·72 per 1,000 compared with 15·86 in 1901. The decrease in mortality was well marked in both valleys, but the districts of Darrang and Goalpara in the Brahmaputra Valley recorded the high rates of 25·71 and 27·54 per 1,000. About four-fifths of the total number of deaths in Goalpara were ascribed to fevers. Of the 77,679 deaths registered under fever 6,333 were from *kala-azar*. The disease was again very prevalent in Darrang and Nowgong, which returned 3,391 and 1,697 deaths respectively.

The death-rate from dysentery and diarrhœa fell from 2·19 to 2·13 per 1,000. There was the same remarkable differences in the rates of the various districts, ranging from 0·19 in Goalpara to 4·55 in Lakhimpur.

Madras.

In the Madras Presidency the year 1902 was one of good rainfall and reduced food prices, and was marked by an increased birth-rate and reduced mortality. There was an increase in the births of over 87,000 and the birth-rate rose from 25·1 per 1,000 to 28·2. Notwithstanding this improvement, registration of vital statistics is still far from accurate, and this is further shown in the large differences which appear in the ratios prevailing in neighbouring districts, *e.g.*, the birth-rate of 22·4 in North Arcot contrasts unfavourably with that of 31·1 in Chingleput. The mortality in 1902 was less by 63,703, the total number of registered deaths being 732,437 or 20·2 per 1,000 of population, against 21·3 in 1901. Ten of the 22 districts registered a death-rate in excess of the Presidency rate, the highest being 42·4 in Madras City, followed by 32·6 in Bellary and then 26 per 1,000 in Nilgiris, Tanjore and Tinnevelly.

The diminished rate of mortality is chiefly accounted for under cholera, from which the deaths fell from 81,370 or 2·2 per 1,000 to 29,769 or 0·8 per 1,000. This rate was exceeded only in six districts, and of these Bellary, Tinnevelly, Tanjore and South Arcot contributed 16,475 of the total cholera deaths, their respective rates being 3·2, 2·7, 2·2 and 1·2. As regards the influence upon cholera of protected public water supplies, the Sanitary Commissioner states that in the case of six towns which have been furnished with a

protected water-supply the death-rate from cholera has been reduced from a five year average of 4·1 per 1,000 to 1·8.

The incidence of small-pox was lighter than in the preceding year by 1,235 deaths, the death-rates being 0·7 and 0·8. The Sanitary Commissioner shows by a comparison of death-rates that during the last ten years good progress has been made in reducing the mortality from this disease, and the question of reorganizing the vaccination staff with a view to greater efficiency was under the consideration of the local Government. In the decade ending 1882 the small-pox mortality was 1·9 per 1,000, in that ending 1892, 1·4, and in that ending 1902, 0·3. Over 57 per cent. of the small-pox deaths registered in the year under notice occurred among children under ten years of age.

The deaths attributed to fever decreased from 294,854 or 7·90 per 1,000 to 277,689 or 7·7. The question of adopting measures for preventing the prevalence of malarial fevers in the Presidency has long been considered, but no appreciable progress has been made. "The prevalence of wet cultivation in the immediate neighbourhood of dwellings," the Government remark, "both in urban and rural tracts, and the heavy costs involved in putting an end to such cultivation, render the future prevention of malarial fevers far from hopeful, but a reduction in mortality may be hoped for from the extended use of quinine."

Dysentery and diarrhœa were also less fatal during the year, the number of deaths having fallen from 42,084 or 1·13 per 1,000 to 36,633 or 1·01. These diseases appear to be much more fatal in municipalities than in rural areas, the death-rate in the former being 4·5 per 1,000, against a rate of only 0·7 in the latter. In Madras municipality a death-rate of 6·7 was attributed to these diseases.

During the year 10,795 deaths from plague were registered, and of these 68 per cent. occurred in the district of Bellary. In the previous year 3,035 plague deaths were reported in the Presidency. In all cases the infection is said to have been imported from territories (chiefly Mysore) beyond the control of the Government of Madras. The Sanitary Commissioner remarks that "so long as Madras territory is liable to be repeatedly invaded from an area where no organization exists the chances of successful resistance to the general spread over the whole Presidency are much lessened."

The number of births registered in the Presidency of Bombay during 1902 was 631,393, giving a birth-rate of 34·16, which is a marked increase on the low rates obtained in the famine years of 1900 and 1901, viz., 26·87 and 25·19. Owing to the prevalence of plague the death-rate rose from 37·12 to 39·04, or nearly 5 per 1,000 in excess of the birth-rate. Eleven out of the 25 districts recorded a higher mortality than in the previous year, and in 13 districts the recorded death-rates exceeded the birth-rates.

There was comparatively little cholera in the Presidency during the year, only 3,229 fatal cases having been recorded against 13,600 in 1901 and 163,889 in 1900. Seven districts were entirely free, and six others practically so, as only one death was reported from each. The disease, however, was somewhat severe in Karachi and Hyderabad, where the death-rate reached 4·47 and 1·09 respectively.

The mortality from small-pox was less than half that recorded in 1901. There were only 2,189 deaths to which all the districts but five contributed. But only in one district (Kanara 1·32) did the death-rate reach 1 per 1,000. Sixty-five per cent. of the deaths occurred amongst children under ten years of age.

Fever was responsible for 270,845 deaths or 14·66 per 1,000, as compared with 291,951 or 15·80 in 1901. In the districts of Ahmedabad (39·50), Broach (26·05), Larkana (25·19), Kaira (20·60), Panch Mahals (20·33) and Thar and Parkar (19·75) high rates were again recorded, which is attributed to famine causes to a certain extent.

Dysentery and diarrhœa accounted for 58,682 deaths, or 1,516 more than in the previous year, the death-rate being 3·26. The highest district rate was recorded by Khandesh (8·12) followed by Sholapur (6·37) and in six others the Presidency rate was exceeded.

The mortality from plague during the year was the highest recorded since its first appearance in 1896. The fatal cases rose from 128,259 or 6·94 per 1,000 in 1901 to 184,752 or 10·0. All the districts except Upper Sind Frontier were affected. Those most affected were Satara (29·37), Dharwar (29·38), Belgaum (27·42), City of Bombay (18·13), Khandesh (17·58), Kaira (11·71), and Nasik (11·11). In the other districts the death-rate from plague varied from 8·89 in Poona to 0·01 in Larkana and Sukkur. The most fatal month was December, when 30,507 deaths were registered. Over 10 per cent. of the towns and villages were affected by the epidemic, against 6·10 per cent. in 1901.

Berar.

The year 1902 was generally a healthy one in Berar, and except for plague there was little or no epidemic disease. The prices of food grains were easier than in the previous year, and returning prosperity resulted in a large increase in the number of marriages, which must have influenced the birth-rate, as it reached the abnormally high figure of 56·9 per 1,000 of population, the highest recorded during the past 31 years. The increase was most marked in the Buldana and Wun districts, where the birth-rates reached 62·7 and 59·5 per 1,000 respectively. The rates of the remaining districts were somewhat lower than the provincial rate, but higher than the provincial rates of the preceding 31 years. The death-rate was 32·8 per 1,000, which, though higher than that of the previous year (27·6), was 13·9 less than the quinquennial mean.

Except for one small outbreak in a village in the Buldana district, the province enjoyed immunity from cholera during the year. The number of deaths was 16, or one less than in 1901. The disinfection of the drinking-water supply with permanganate of potash and fumigation of houses are said to have helped the speedy disappearance of the disease.

Small-pox accounted for 327 deaths, or 137 more than in the previous year. Of these, 179 were contributed by Buldana district and 82 by Ellichpur; 63 per cent. of the deaths occurred among children under 10 years of age.

The mortality ascribed to fevers was slightly lower than in the previous year, the death-rate being 13·7 per 1,000 against 13·9. From dysentery and diarrhœa also there was a trifling decrease in the death-rate, viz., from 4·4 to 4·2.

Plague gained a footing in the province during the year, and the epidemic resulted in 4,188 deaths, of which Akola district returned 1,639 and Buldana district 2,507. It was only after the disease had wrought havoc among them that the people would consent to the adoption of any measures for preventing it spreading. "Experience, however, has taught them that their only safety lay in vacating an infected village as soon as possible, and to this most of them now readily resort, with the happiest results."

IV.—JAILS.

Sickness and mortality in 1902.

The health of the jails of British India, which had shown improvement in the previous year, still further improved in 1902. On the whole there was much less sickness among the prisoners, and the only diseases with increased admission rates were tubercle of the lungs and enteric fever. The death-rate fell from 25·16 per 1,000 of average strength in 1901 to 22·48 in 1902. The three diseases, dysentery, tubercle of the lungs, and pneumonia, which caused more than half the deaths in the previous year, were again credited with 57 per cent. of the total deaths. There were only 24 deaths from cholera, against 106 in the previous year. From tubercle of the lungs the death-rate was the highest recorded during recent years, viz., 4·25 per 1,000 against an average for the ten years 1891–1900, of 2·98. Although plague was so widespread and fatal during the year there were only 20 deaths from the disease in the jails.

The following statement shows the sickness and mortality among all classes of prisoners in the jails and subsidiary jails of the various provinces for 1902 as compared with the previous year :—

Provinces.	1901. Ratio per 1,000 of Average Strength.			1902. Ratio per 1,000 of Average Strength.		
	Admissions.	Daily Sick.	Deaths.	Admissions.	Daily Sick.	Deaths.
Bengal	1,096	38	27·6	1,041	39	25·4
United Provinces of Agra and Oudh.	840	40	24·2	734	35	20·4
Punjab	1,253	38	26·9	1,137	35	25·0
North-West Frontier Province...	973	32	12·8	1,038	32	28·0
Burma	547	26	15·2	537	25	15·9
Central Provinces	867	28	27·5	972	32	24·8
Assam	1,029	42	24·5	857	39	29·9
Coorg	654	35	165·9	320	32	48·0
Madras	476	24	21·7	390	22	17·8
Bombay	964	34	35·0	682	28	28·2
Berar	676	21	24·9	784	18	17·9
India	882	34	25·2	793	32	22·5

Bengal.

Notwithstanding an increase in the jail population of Bengal during the year, and consequent overcrowding in some of the jails, the death-rate among all classes of prisoners (25·4 per 1,000) was lower than in any of the previous ten years except 1898 and 1899. The jail death-rate was considerably below that of the whole population (33·4), which is satisfactory "considering that a large proportion of the jail population must always be drawn from those classes whose vitality is considerably below the normal standard." Of the 40 district jails 21 showed a distinct improvement in health, and the death-rates of the central jails, with two exceptions, were very low. There were only nine cases of cholera, all fatal, among the prisoners. Five jails had only one case, and two jails had two cases each, "thus showing that the threatened outbreak was quickly grappled with and not permitted to spread." There was a considerable falling off in the mortality from dysentery, and one of the most satisfactory features of the year is that 20 jails had no deaths from this once most dreaded of all jail diseases. Next to dysentery, tubercle of the lungs, &c., and pneumonia were the most fatal diseases. In spite of the prevalence of plague in many districts the disease attacked only two jails, viz., Alipore jail, which

recorded five cases, three fatal, and Darbhanga, one fatal case. In both jails energetic measures were taken to prevent the disease spreading, and the outbreaks were over in a few days.

United Provinces of Agra and Oudh.

The health of the prisoners in the United Provinces of Agra and Oudh was exceptionally good during the year 1902. Among all classes of prisoners the daily average sick rate per 1,000 of average strength was 34·9 against 39·5 in the previous year, and the death-rate 20·4, which was the lowest recorded, with the exception of that for the year 1893. Of the 56 jails in the provinces there were no deaths in three, and in 12 out of 25 in which the mortality was higher than the provincial average, the death-rate did not exceed 25 per 1,000. In the previous year the health of the three district jails of Allahabad, Moradabad and Banda, with death-rates between 50 and 60 per 1,000, caused much anxiety, but there was a satisfactory improvement in 1902; and in the Bareilly, Fatehpur and Jaunpur district jails, which were formerly considered unhealthy, the mortality was below the provincial average. There was very little cholera among the prisoners, only 16 cases and 9 deaths having been recorded, against 47 cases and 32 deaths in 1901. Only the two central jails of Benares and Ghazipur were affected. The epidemic in the Benares prison, resulting in six deaths, was checked by the removal of the prisoners from the infected quarters into camp. Of other diseases, dysentery accounted for 133 deaths against 163 in 1901, tubercle of the lungs, &c., 92 against 106, and pneumonia 61 against 67. Isolation of dysentery and tubercle cases is reported to have been attended with good results in certain jails.

Punjab.

The standard of health among prisoners in the Punjab during 1902 was higher than in the previous year. The ratio of constantly sick declined from 38 to 35 per 1,000, and, notwithstanding that there was a rise of nearly 8 per 1,000 in the death-rate of the free population, the mortality of the jails decreased from 26·95 to 25·06. Out of 28 jails, there were no deaths in four, and in seven others the death-rate was well below the provincial average. Of the remaining 17 prisons, the death-rate was higher than the provincial average in 14. No cases of cholera occurred in any of the jails, and there was a considerable decline in the death-rate from dysentery. On the other hand, tubercle of the lungs, &c., continued to increase, but it is noteworthy that 30 of the deaths out of 57 under this head occurred amongst prisoners who were admitted in bad or indifferent health. Steps were being taken to prevent the spread of tuberculous disease by the provision of isolation wards, and improvements generally in jail accommodation. Pneumonia was also more fatal. The Inspector-General believes the incidence of this disease to be largely affected by the personal hygiene of prisoners, and he has urged all classes of jail officers to give the matter their personal attention. In spite of the wide-spread prevalence of plague throughout the province, only three deaths from the disease occurred among the convict population. The Inspector-General states: "The large share of immunity enjoyed is no doubt ascribable to the generally good sanitary state in which the jails are maintained and to the precautions taken by most officers to prevent the introduction of the disease among the prisoners."

North-West Frontier Province.

The general health of the prisoners in the North-West Frontier Province during 1902 was on the whole satisfactory. The average daily sick per 1,000 of strength was 32, exactly the same as in 1901, and the death-rate rose from 12·7 to 28·02, which was 3·60 above that of the free population. The higher mortality was mainly due to the bad health of prisoners on admission. Of the 32 who died, 16 were admitted into jail in bad or indifferent health, and six cases were described as accidental or coincidental, such as fracture of the skull, rupture of spleen, heat apoplexy, &c. There was no cholera, and only four deaths from tuberculous disease of the lungs. Malaria as usual figured largely in the causation of disease, but prophylactics were issued in the autumn months with satisfactory results.

Burma.

In Burma the health of the prison population was again satisfactory. The admission and constantly sick ratios were the lowest on record, but there was a slight rise in the death-rate, from 15·19 per 1,000 in 1901 to 15·88. There were no deaths in seven out of the 32 jails and in the European side of the Rangoon jail, and in nine others the mortality was below the provincial rate. There was a marked improvement in the Moulmein jail, which for years had been notoriously unhealthy, the death-rate having fallen to 21·44. For the first time in 10 years the Burma jails were free from cholera. Of the other chief diseases, malarial fevers and bowel complaints were the most prevalent, while

tuberculous diseases were the most fatal, the death-rate being nearly 4 per 1,000, or a fourth of the total mortality. Separate wards for the treatment of tubercular cases existed in 10 jails, and the question of the desirability of a separate tubercle jail was under consideration.

Central Provinces.

The health of the prisoners in the Central Provinces during 1902 was on the whole good. There was no overcrowding to any considerable extent. There was an increase in the admission and daily sick rates, which was partly due to greater liberality in the admission of sick men to hospital, but the mortality (24·82) was nearly 3 per 1,000 less. In five out of the 19 jails there were no deaths. Malarial fevers were the chief causes of sickness, while bowel diseases furnished the largest number of deaths. Of the total 20 deaths from dysentery, just a half occurred in Jubbulpore central jail. A special investigation was made into the sanitary conditions of this jail and the circumstances which had conduced to the high mortality of 1901. As a result a change in the diet has been effected and structural improvements were in progress. The death-rate at this jail fell from 49·70 in 1901 to 40·36. From tubercular diseases the deaths rose from nine to 15, and of these Jubbulpore contributed seven. The separate treatment of patients suffering from these diseases has been under consideration, and the construction of isolation wards in the three central jails was being undertaken. All the jails were free from cholera during the year.

Assam.

Though the prisoners of Assam had lower ratios of sickness than in the previous year, their mortality was higher, the excess being chiefly due to an outbreak of beri-beri at Gauhati, which occurred during the last four months of the year and occasioned six deaths, or half the total mortality in that jail. The daily average sick-rate fell from 41·8 in 1901 to 38·6 in 1902, the decrease being due to a marked decline in the ratio of admissions from dysentery and malarial fever, and the death-rate rose from 24·5 to 29·9. There was only one case of cholera, which occurred in the Silchar jail and terminated fatally. Special precautions were taken in the case of prisoners suffering from tubercle of the lungs. In only three of the jails was the average strength over 100, and these contributed 35 out of the total of 45 deaths. In 14 jails no deaths took place.

Madras.

A high standard of health was maintained throughout the year 1902 among the prisoners in the Madras Presidency. The death-rate was only 17·8 per 1,000 against 21·7 in the previous year, while the ratio per 1,000 of daily average sick (24·1) was the lowest recorded for several years. "These very satisfactory results" the Inspector-General states, "are in a great measure ascribable to the care and attention of Medical Officers and Superintendents and their personal supervision of all matters relating to diet, labour, and personal hygiene." In none of the seven central jails did the mortality exceed 30 per 1,000, and of the district jails only in Cuddalore and Tanjore and the Criminal Leper Ward, Madras, was this ratio exceeded. In the case of those jails where mortality was high, the cause was stated to have been the poor health of the prisoners on admission. All the jails enjoyed an immunity from cholera except the Palamcottah district jail, which returned three cases, all of which proved fatal. The disease was prevalent in the town and district at the time. The number of admissions to hospitals and of deaths from tubercular diseases declined. Tuberculous patients are treated separately; measures are taken for the thorough disinfection and destruction of their excreta; open air treatment is as far as possible enforced. Plans were under consideration for the provision of special wards. Plague was prevalent in the vicinity of several jails and was a constant source of anxiety, but only one prisoner was attacked, who eventually recovered.

Bombay

The health of the prisoners in the Bombay Presidency during the year 1902 was satisfactory. Overcrowding occurred in 9 out of the 15 jails, and was relieved by transfer, and by the use of tents, temporary sheds, workshops, &c. The daily average sick rate fell from 34 to 28 per 1,000 of average strength, and the death-rate rate from 35·0 to 28·2. Admissions to hospital for malarial fever were much fewer than in 1901, numbering only 1,928 against 4,340. The decline was most marked in the Central Prison, Yeraoda, where the cases fell from 2,709 to 468. During the year the Medical Officer of this jail instituted a quinine gang, to each of whom was given five grains once a week, and the diminution in admissions was ascribed to this treatment. There was only one case of cholera, and this occurred in the Thana Special Prison, and did not prove fatal. In the Sind gang the proportion of pneumonia deaths was again high.

Of the total 20 deaths which took place among the gang 14 were due to pneumonia. In connection with this disease new barracks with improved ventilation have been built. There was also much sickness and mortality from pneumonia in the Hyderabad Central Prison, but many of the men who developed the disease are reported to have previously suffered from scurvy. Plague occurred in five jails, the most in Bombay City, where there were 16 cases and 9 deaths out of a total of 24 cases and 12 deaths from the disease.

Berar.

The general health of the prison population of Berar in 1902 was satisfactory. The ratio per 1,000 of daily average sick was 18 against 21 in the previous year, and the death-rate 17·87 against 24·94. The sick were freely admitted into hospital, and the mortality was slightly below that of the general population. There was no cholera in any of the jails. Plague was prevalent during the year in the station and district of Buldana, but the disease was kept out of the jail. Precautionary measures were taken to guard against its introduction: all newly admitted men from infected localities were kept under observation and in segregation for 10 days, all the prisoners and the jail establishment were inoculated, and the mouths and outlets of drains were so fixed as to prevent the ingress of rats. There was no overcrowding in the jails.

V.—VACCINATION.

General results.

During 1902-03 there were 8,431,564 persons vaccinated in the several provinces of India, being an increase of 395,120 on the number of the previous year. The increase was spread over all the provinces except the Punjab. Most progress was made in Bengal, the United Provinces and Bombay; and in several other provinces much more work was done than in the previous year. According to age, 3,707,644 children under one year of age, and 3,160,398 children between the ages of one and six years were successfully vaccinated during the year. The proportion of population protected against small-pox by the year's operations ranged from 58·4 in Coorg to 24·2 in Bombay Presidency. In the vaccination of infants the best results were obtained in Berar, the Central Provinces, Ajmer-Merwara, the Punjab, the North-West Frontier Province, and the United Provinces, and the worst in Burma and Coorg.

Statement showing the total number of persons successfully vaccinated during the year 1902–03 :—

Province.	Population among whom Vaccination was carried on.	Number of Persons vaccinated.	Ratio of successful Vaccinations per 1,000 of Population.	Number of Children successfully vaccinated.		Percentage of Annual estimated Births at 40 per 1,000 of Population successfully vaccinated.
				Under One Year of Age.	Between One and Six Years of Age.	
Bengal	74,764,424	2,781,972	37·21	894,791	1,462,913	29·92

Ajmer-Merwara	476,912	12,992	27·01	10,952	1,427	57·40
TOTAL	236,747,885	8,431,564	33·14	3,707,644	3,160,398	39·15

Bengal.

Satisfactory progress was made in vaccination work in the province of Bengal during the year 1902–3. The results show an increase of 119,146 operations over the number for the previous year, and a rise in the proportion of persons successfully vaccinated from 34·24 per thousand to 37·21. Out of the 49 districts in the province, including the Tributary States of Orissa and Chota Nagpur, there was an increase of vaccinations in 32 and a decrease in. 17. The increase in some districts was attributed to the prevalence of small-pox, and in others to the greater activity of the staff. It is estimated that 36·05 per cent. of the infants available for vaccination were protected during the year in the province as a whole, against 32·06 in the previous year. "There is thus," the Sanitary Commissioner remarks, "some improvement which must be gradual and slow, having regard to the fact that in most districts the people are very reluctant to have their children under one year vaccinated." Of the total 2,592,177 primary vaccinations,

214,764 were performed with calf lymph, 399,205 with lanoline lymph, and 1,978,208 by the arm to arm process, the ratio per cent. of success under each of these methods being 98·13, 96·75 and 98·38 respectively.

There was a considerable falling off in vaccination work in Calcutta, the total number of persons vaccinated (17,534) being less than half the number in the previous year (35,630). The decrease was partly due to the subsidence of small-pox, and partly to the district health officers and vaccinators being new to the work, and to constant changes in the Department, the vaccinators throwing up their appointments to take others which were more remunerative or congenial. In the two previous years, however, small-pox was prevalent, and special efforts were made to get people vaccinated, but making all due allowance the Health Officer considers the results very unsatisfactory.

United Provinces of Agra and Oudh.

In spite of the fact that plague was much more widespread in the United Provinces of Agra and Oudh during the year under report than in the preceding year, the number of persons vaccinated continued to rise and reached the total of 1,665,253, an increase of 85,058 on the figures of 1901–2, and of 73,266 in the number of successful primary vaccinations. The increase was spread over 37 of the 49 districts, the most conspicuous being Sitapur and Ballia with increases of 25,566 and 16,028 respectively. The percentage of successful primary cases in which the results were known rose slightly, from 97·71 to 97·90. Bovine lymph was very little used, only 21,065 operations being performed with it, with a percentage of success of 98·73. The Vaccination Act is in force in all municipalities and cantonments, but the rules are said to be enforced with a varying degree of energy in different places.

Punjab.

There was a slight falling off in the number of vaccinations performed in the Punjab during 1902–3, but it was entirely under re-vaccinations, as the primary operations rose from 511,121 in the previous year to 582,626. The greater part of the decrease occurred in the district of Kangra and the Simla Hill States where, although plague was not present, the people opposed vaccination, fearing that they would be subjected not to vaccination, but to anti-plague inoculation. As regards Kangra, the Sanitary Commissioner remarks, "re-vaccination has been so extensively performed in this district in previous years that there is no need for a large number to be done at present." Of the 555,608 successful primary vaccinations, nearly 85 per cent. were infants under one year of age. The Vaccination Act was not extended to any new town during the year. A comparison of the statistics of the large towns in which the Act is in force shows, the Sanitary Commissioner states, that in several a greater proportion of infants remained unvaccinated during the year. "The prevalence of plague," he says, "has doubtless interfered with the work, but the principal causes of the slow progress of vaccination in towns are the apathy of the people and the want of interest on the part of members of Municipal Committees."

North West Frontier Province.

Much improvement was made in vaccination work in the North-West Frontier Province during 1902–3, the total number of operations being 90,293 or 19,300 more than the previous year's total. Of these 82,352 were primary cases with a percentage of success of 93·54. The increase was spread over all the five districts of the province. Of the total successful primary vaccinations, 53 per cent. were infants under one year of age, and the number of persons successfully vaccinated per 1,000 of population was 39·85, against 29·92 in the previous year. Both animal and preserved vaseline lymph were used during the year, the former showing in primary cases a percentage of success of 93·4, and the latter of 89·47. Out of the ten municipal towns in the province, the Vaccination Act is in force only in two, viz., Dera Ismail Khan and Bannu. The question of extending the Act to Peshawur City, where the proportion of children vaccinated is lower than in any other town of importance in the province, was under consideration.

Burma

With an increase in the average number of vaccinators the operations in Burma rose from 360,224 to 381,773. The increase however was entirely in Upper Burma as in Lower Burma there was a falling off, which was attributed chiefly to the attitude of the people who have a predilection for inoculation. "They fully understand," it is reported, "that vaccination is not compulsory outside municipal limits, nor inoculation illegal, so that villages which willingly submitted to vaccination in past years now hold aloof altogether on one pretext or another." A closer supervision of the work of vaccinators and the infliction of punishments for false returns are also advanced as reasons for the decline. Primary vaccinations rose from 333,791 to 355,013, but the percentage of success

was lower than in the previous year, being 86·9 against 90·1. The protection of infants remained very backward in the province. Out of 308,583 successful vaccinations only 26 per cent. were operations on children under one year of age, and only 19 per cent. of the births estimated at 40 per 1,000 of the population were successfully vaccinated.

Central Provinces.

Good progress was made in vaccination work in the Central Provinces in 1902–3. The aggregate number of vaccinations reached 464,051, the percentage of success in primary operations being 97·13 and in re-vaccinations 85·14. All the districts except Narsinghpur and Nagpur showed an increase in primary vaccinations. In these two districts and in several other towns and villages the prevalence of plague interfered with vaccination, and but for this disturbing influence and the withdrawal of some vaccinators for plague duty, the record of the year would have been even more successful. In Bhandara, where excellent work was done, the increase amounted to 86 per cent., and in Wardha to 54 per cent. The increase was mainly due to the very high birth-rate of the year combined with the low infant mortality; but a contributory cause was the commendable activity shown by the vaccination staff in most districts. Of 357,679 children under one year available for vaccination (that is, the total births less deaths under one year in 1902–3) 79·37 per cent. were successfully vaccinated. The Vaccination Act was not extended to any additional town during the year, but steps were being taken to improve vaccination work in municipal towns where hitherto there has been no attempt to apply the provisions of the Act.

Assam.

Vaccination progresses steadily on the whole in Assam. The results of 1902–3 show an increase of 23,294 operations as compared with the previous year. The increase however was not general, as in Cachar there was a decrease of nearly 30 per cent. and a considerable falling off in Goalpara. Inoculation is still carried on, especially in Cachar and Sylhet where the people are averse to vaccination. The Deputy Commissioner of Cachar says: "I regret to have to state that in the interior of the district the people prefer inoculation, and I have no doubt that the chronic state of small-pox in the villages is mainly due to the existence of professional inoculators." The percentage of successful primary operations was 97·90 or almost the same as in the previous year. Vaccination of children under one year of age increased, but even with the progress made the figures fell far short of the registered births. In towns where the Vaccination Act is in force more than 80 per cent. of the children available for vaccination were protected. Good work continued to be done at the Animal Vaccine Depôt at Shillong. The quality of the lymph "was generally excellent throughout the year."

Madras.

The total number of vaccinations performed in the Madras Presidency during 1902–3 was 1,332,209, representing an increase of 7,103 cases as compared with the preceding year. The increase was entirely in local fund areas, as municipalities showed a decrease of 11,210, due to the prevalence of plague, the disappearance of small-pox, the neglect of re-vaccination and paucity of cases available. In six districts there was a decrease, the explanation for which in three cases was insufficiency of staff. The percentage of success remained almost stationary being 90·7 against 91·0 in the preceding year. There was an increase of 25,612 in the number of children under one year of age successfully vaccinated, but the total number represented only 25 per cent. of the estimated births. Vaccination is compulsory in all the municipalities, and in these an average of 67 per cent. of the available children were afforded protection, more than a half securing a ratio of 75 per cent. Compulsory vaccination was also in force in some village unions of a few districts throughout the year, but it is as yet too early to say anything about its effects. More than a third of the total operations were performed with animal lymph, giving a percentage of success of 87·4; but the best results were obtained as usual from calf to arm vaccination with a percentage of success of 98·5.

Bombay.

In the Bombay Presidency the number of operations, which had been falling in the two previous years, rose in the year under notice to 578,885, or 10 per cent. more than in 1901–2. Out of 537,744 persons primarily vaccinated 93·05 per cent. were successful. Exclusive of Native States and Aden, which are not under the supervision of the Vaccination Department, 364,513 infants, or 71·85 per cent. of the available children were successfully vaccinated. Animal and human lymph were used in the Presidency, and a few operations were performed by glycerinated lymph and lanoline paste. In the Gujarat registration district vaccination was carried on entirely by human lymph, and in the

Presidency circle this lymph was not used. The best results were obtained from human lymph, the ratios of success in the Registration districts ranging between 86·67 and 95·57 per cent. No inoculation was reported to have been practised anywhere during the year, and no instances were reported of any disease having been communicated through vaccination.

Berar.

Satisfactory progress was made in vaccination work in Berar during the year 1902–3. The results show an increase in primary cases of 35,263, and the percentage of successful primary vaccinations was 96·8, slightly higher than in the preceding year. The number of revaccination cases fell by 14,617, this large decrease being due to the vaccinators having to devote more time to primary work on account of the high birth-rate of the year. The Vaccination Act is in force in all the municipalities, but owing to severe epidemics of plague in three of them, the average proportion of infants successfully operated on fell by 10 per cent. The Sanitary Commissioner gives some striking figures showing the efficacy of vaccination in diminishing small-pox mortality in the province: the ratio of successful vaccinations per 1,000 of population has risen from 8·92, the mean of the five years ending 1872–3, to 35·54, the mean of the five years ending 1902–3, and the mortality from small-pox during the same periods has declined from 2·02 to 0·15 per 1,000.

VI.—MEDICAL INSTITUTIONS.

Civil Hospitals and Dispensaries.

The following comparative statement shows the number of hospitals and dispensaries under official control open in the several provinces of India during 1902 and the previous year, and the number of patients under treatment :—

Provinces, &c.		Number of Institutions.	Number of In-door Patients.	Number of Out-door Patients.	Total Number of Patients.
Bengal	1902	574	52,237	4,110,539	4,162,776

TOTAL	1902	2,459	372,780	22,039,114	22,421,894
	1901	2,323	362,373	20,597,137	20,959,510

Bengal.

The number of dispensaries at work in Bengal outside Calcutta during 1902 was 24 in excess of that of the previous year, and the total number of patients treated rose by nearly half a million, or 12 per cent., the increase being chiefly in out-patients. "The large increase," the Inspector General states, "was no doubt influenced by the unhealthiness of the year, but at the same time the local officers report that it was greatly due to the growing popularity of the dispensaries which have now been improved in many respects." An encouraging feature in the returns is the increased popularity of the dispensaries among female patients who numbered 68,239 more than in 1901, which was greatly due to improved arrangements for their treatment. The attendance of children also increased by 129,582. There was an increase of patients under all the chief diseases except small pox ; cases of cholera rose from 8,143 to 11,626, and of malarial fever from 653,997 to 758,128. The death-rate amongst the in-patients was 104·7 per 1,000, against 106·7 in 1901. Plague patients (in and out) numbered only 1,064, although 32,967 deaths from the disease were reported in the province during the year. Another satisfactory feature in the working of these institutions is the continuous increase in the number of operations which rose from 157,377 to 171,647 ; of these 214, or 0·12 per cent., were fatal. Among the more important operations there were 3,203 cases of extraction of the lens.

The following statement shows the number of in-door and out-door patients treated in the several hospitals and dispensaries in Calcutta and Howrah during 1902 and the previous year :—

NAME OF INSTITUTION.	1901.				1902.			
	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.
Medical College Hospital	4,751	37,282	42,033	138·9	5,447	39,764	45,211	144·1

Howrah General Hospital	1,798	12,844	14,642	241·9	2,077	12,362	14,439	242·6
GRAND TOTAL	25,989	253,615	279,604	153·1	29,063	260,769	289,832	142·9

At the various medical institutions in Calcutta there was an increase of 7,154 in out-door patients and of 3,074 in in-door patients, an advance which is considered satisfactory, as the public health of the city was better than in 1901. Of the increase of 10,228, nearly a half were women and children. The increase in in-patients was shared in by all the institutions which accommodate this class of patients except the Campbell Hospital, "in which the attendance is always highest in times of scarcity and great sickness." There was an increase of patients treated under nearly all the major heads of disease as compared with the previous year. The rise in cases of cholera from 442 to 647 corresponded with the greater prevalence of the disease in the town. Plague cases rose from 458 to 554. Among the in-patients there were 4,155 deaths, giving a ratio of 142·9 against 153·1 in 1901. The total number of operations performed during the year was 28,385, against 27,552 in 1901, and death resulted in 200 cases against 207.

United Provinces of Agra and Oudh.

There was an increase of four in the number of dispensaries at work in the United Provinces of Agra and Oudh during 1902, and of 15,043 in the number of patients. The increased attendance, however, was entirely in out-patients, as the in-patients were fewer than in the previous year by 116. Among the in-patients there were 2,420 deaths against 2,950, and the death-rate fell from 53·3 per 1,000 to 43·8. Of the diseases for which the patients were treated there were 1,069 cases of cholera, as compared with 2,449 in the previous year, and cases of malarial fever increased by 13,338. The number of surgical operations was 182,548, and of these 155,656 were successful and 359 were fatal. Among the operations, 5,567 were for cataract, with a percentage of success of nearly 88. In reviewing the Inspector-General's report the Government state: "No department of Government has better earned, or more fully won, the gratitude of the people than the medical department of these provinces. With very imperfect means it has achieved results which may not look great in the light of the latest achievements of science in the West, but which are really very remarkable, and which compare favourably with results in more than half the civilized world at the present time, and in England within the memory of men who are not yet old."

Punjab.

There was an increase of six in the number of hospitals and dispensaries at work in the Punjab during the year 1902, the total being 249. Of the 3,019,126 patients under

treatment, which is 5,885 less than the number treated in the previous year, 50,138 were in-patients, of whom 2,385, or 47·5 per 1,000, died, against a mortality of 2,344, or 45·4, in 1901. The number of in-patients was 2·7 per cent. less than in the previous year, the diminished attendance being partly attributed to the prevalence of plague. Of the total number of patients treated the largest falling off occurred among those treated for malarial fevers (decrease, 74,734 cases) and diseases of the lungs and respiratory organs (decrease, 9,001 cases), while there were very large increases in the attendance of patients for classes of disease whose prevalence does not vary so much with variations in the rainfall and temperature. The number of patients treated for eye diseases increased by 60,550, and for ulcers by 13,089. Only 24 cases of cholera were treated. In the number of surgical operations performed (153,408) there was an increase of 1,571, which is all the more satisfactory seeing that there was a falling off in in-door and out-door patients. Of the total operations 148,213 resulted in cure and 254 were fatal. There were 5,700 operations for cataract, and of these 4,683 were successful.

North-West Frontier Province.

Returns were received from 37 dispensaries in the North-West Frontier Province during the year 1902, and at these 521,759 patients were treated, being an increase of 65,135 on the attendance in the previous year. Of the 7,624 in-patients, 5,701 were cured and 336 died. There was only one case of cholera, but there was a slight increase of small-pox cases and a marked increase in cases of malarial fever, to which all the districts of the province contributed with the exception of Dera Ismail Khan, where the cases were less by 3,528. The total number of operations performed was 21,689, or 2,039 more than in 1901. The results showed 21,331 cases as cured and 61 deaths.

Burma.

A total of 129 hospitals and dispensaries under Government supervision were working in Burma during 1902 or ten more than in the previous year. At these 925,414 patients were treated, being an increase of 28,187 over the figures for 1901. Of the 42,168 in-door patients, more than three-fourths were returned as cured, and 2,663 or 63 per 1,000 died, a somewhat lower mortality than in the previous year. As usual malarial fevers headed the list of diseases for which patients sought treatment, next in order being ulcers, diseases of the eye, worms and diseases of the digestive system. Cholera was slightly more prevalent, and the cases rose from 250 to 278 ; there was also a small increase in cases of small-pox. During the year 669 cases of beri-beri were treated in the Rangoon General Hospital ; of these 382 were in-door patients, of whom 196 died. The number of surgical operations continued to increase, and in 1902 aggregated 22,410. Amongst the patients operated on 21,351 were cured and 144 died.

Central Provinces.

During the year 1902 there were 103 dispensaries at work in the Central Provinces, and at these the number of patients, both in-door and out-door was practically the same (1,348,000) as in the previous year. Considering the healthy character of the year and the disturbing prevalence of plague in several towns the maintenance of the attendance is evidence of the popularity of the institutions. In most of the dispensaries arrangements for the separation of male and female out-patients while being examined and prescribed for now exist ; but it is not always easy, the Administrative Medical Officer of the provinces says, to induce female patients to avail themselves of these arrangements. As regards the number of patients treated for different diseases, the most important variations as compared with 1901, were an increase of 28,530 under eye diseases, a decrease of 17,912 under malarial fevers and of 9,457 under skin diseases. The number of surgical operations performed was 33,802 but a large majority were of a trivial nature. Of the total, 32,821 were cured and 71 died. Cataract operations declined from 904 to 810.

Assam.

In the province of Assam there were 128 dispensaries open during 1902 or three more than in the previous year. There was a further large increase of 86,649 patients treated. The number of in-patients rose from 6,539 to 6,883, and of these 4,110 were cured and 738 died, giving a death-rate of 110·4 per 1,000 against 121·1 in 1901. It is stated that the people who attend the Assam institutions belong for the most part to the lowest classes of the population, and have recourse to the dispensaries for trifling ailments, and that in the Assam Valley, especially, little confidence in European methods of treatment is shown by the upper and middle classes. Of the various diseases for which the patients were treated the largest numbers were under skin diseases and malarial fever.

Cholera cases numbered 2,571, of which 2,142 were treated in the Sylhet district where the disease was very prevalent during the year. The total number of operations rose from 15,689 to 17,417; but these were mostly of a trivial character, and only 734 were important.

Madras. In the Madras Presidency six more dispensaries were at work than in the previous year, bringing the total up to 485. There was an increase of 242,075 out-patients, and a decrease of 3,122 in-patients, the cause of the latter being plague scare in a few places, and improvement in the general health of the population in others. Of the 61,592 in-patients more than half were cured and 4,321 or 70·2 per 1,000 died, against a death-rate of 91·8 in 1901. Ulcers and diseases of the skin, diseases of the digestive system, and diseases of the eye were the most common complaints treated. Cholera cases declined from 10,833 to 5,141. During the year 163,941 operations were performed, exceeding the number of the previous year by 12,246. The results show that 153,408 were cured and 356 died. Of the more important operations 1,495 were for extraction of lens.

Bombay. The number of medical institutions in Bombay Presidency rose to 312, an increase of 74 on the number at work in 1901. The patients treated increased by 572,673, of whom 6,430 were in-patients. Admissions for malarial fever, diseases of the eye and of the respiratory system, skin diseases, and ulcers rose considerably. Cholera cases fell from 430 to 356; small-pox cases were also less numerous. The number of patients admitted into the hospitals and subsequently found to be cases of plague was 701, of whom 368 died and the remainder were transferred to plague hospitals. Of the total 51,621 in-patients 34,442 were cured, and 6,483 or 126 per 1,000 died, against a mortality rate in the previous year of 106 per 1,000. The surgical operations performed during the year numbered 86,811 with a mortality of 436 or 0·50 per cent. Of the more important operations 879 were extraction of lens.

Berar. The number of hospitals and dispensaries at work in Berar during 1902 was 48, the same as in the previous year, but owing to the exceptionally healthy character of the year and the good physical condition of the people, the number of patients who sought relief fell by 10,520. In the districts of Buldana and Akola, however, the decrease was attributed to plague, which caused a scare and deterred the people from seeking medical aid. Of the 5,780 in-patients 4,757 were cured, and 362 or 63 per 1,000 died, a death-rate which compares favourably with that of 73 per 1,000 for the previous year. There was a noticeable increase in the number of fever and spleen cases. There were no cases of cholera and only 25 of small-pox, but the province generally was remarkably free from both these diseases during the year. The number of patients operated on was 12,413, and of these 12,255 were cured and 31 died.

Lunatic Asylums.

Bengal. At the six asylums in Bengal (viz., Bhowanipore, Dullunda, Dacca, Patna, Cuttack, and Berhampore) 1,289 lunatics, including 278 fresh admissions and re-admissions, were under treatment in 1902, being an increase of 95 on the number of the previous year. In the course of the year under notice 114 patients were discharged as cured, and 44 as improved or otherwise, and 96 died. Compared with the figures of 1901, the number discharged was more by 36, and the mortality more by 35. At the end of the year there were 1,033 persons still under detention, or 24 more than at the close of 1901. The general health of the lunatics was satisfactory during the year The number of admissions to hospital rose from 576 to 604; the average daily number of sick fell from 71 to 66; and the death-rate rose from 61·8 to 93·5 per 1,000 of average strength. There were only two cases of cholera against one in 1901. The majority of the lunatics who died were criminals most of whom were old chronic cases and had been resident in the asylums for years. The cause of insanity was traceable only in 46·4 per cent. of the admissions into the asylums, and 53 cases were ascribed to ganja smoking. The results of the working of dairy farms at the asylums were not so satisfactory as in the previous year. The dairy farms at Dullunda, Dacca and Berhampore continued to work well though they showed a total profit of only £44. The usefulness of the dairy farms, however, is not indicated so much in the profits as in the supply of pure milk and in the congenial work which they afford to the lunatics.

In the Bhowanipur Asylum, containing European and Eurasian patients, included in the above total, the inmates during 1902 numbered 58, or 10 more than in the previous year. Of this number 37 were under detention at the beginning of the year, and 21 were subsequently admitted. In the course of the year 16 patients were discharged, and 5 died, leaving 37 under confinement at the close of the year. As regards the health of the patients during the year, there were only 6 admissions to hospital, against 5 in the previous year. Phthisis was more common and caused four deaths.

United Provinces of Agra and Oudh.

The inmates of the four lunatic asylums (Agra, Bareilly, Benares, and Lucknow) in the United Provinces of Agra and Oudh in 1902 numbered 1,391, including 314 fresh admissions during the year, against 1,362 in 1901. Before the close of the year 183 patients were discharged, of whom 117 were reported as cured, and 72 died, leaving 1,137 under treatment at the end of the year. The cause of insanity was unknown in nearly half (660) the cases under treatment. The general health of the patients was good.

Punjab.

The new Central Lunatic Asylum for the province of the Punjab was opened on the 1st March, 1900, and within that month the patients from the old asylums at Lahore and Delhi were transferred to it, and the two institutions were permanently closed. The total number of lunatics in the Punjab lunatic asylum during 1902 was 627, including 148 fresh admissions, against 610 in 1901. At the end of the year the number was reduced to 503 by the discharge of 85 patients, and 39 deaths. The health of the inmates of the asylum was on the whole satisfactory: the daily average sick fell from 54 to 48 and the death-rate from 114·0 per 1,000 of average strength to 79·4. The cause of insanity was unknown in just over a half (333) of the cases under treatment.

Burma.

The Rangoon Asylum is the only one in the province of Burma, and has accommodation for 416 insanes. The maximum number confined on any one day was 425. During 1902 there were 532 patients in the asylum, including 111 fresh admissions, and the total was reduced at the close of the year to 415 by the discharge of 73 patients for different causes and the death of 44. As regards the general health of the inmates, the daily sick rose from 29 to 33, and the death-rate from 88·0 per 1,000 of average strength to 105·7. There was no epidemic sickness in the asylum during the year. The death-rate was influenced by the low state of health of the insanes on admission.

Central Provinces.

In the two asylums of the Central Provinces (Nagpur and Jubbulpore) there were 357 lunatics under treatment during 1902, an increase of 3 on the number in 1901. In the course of the year 27 patients were discharged as cured or otherwise and 13 died, leaving 317 still under treatment at the end of the year. At both asylums the health of the inmates was poor, partly owing to the after effects of the influenza which was prevalent in the previous year. Of the total 13 deaths, Nagpur recorded 7, being in the ratio of 45·9 per 1,000 of average strength, against 10 or 67·6 in 1901. At Jubbulpore there were 6 deaths, being in the ratio of 39·2 per 1,000, against 10 or 63·3 in 1901. Of the 317 patients under treatment at the end of the year the cause of insanity was unknown in 228 cases.

Assam.

There is only one lunatic asylum in the province of Assam, and this is situated in Tezpur. The total number of lunatics under treatment in the asylum during 1902 was 173, or 25 more than in the previous year. Of these, 43 were fresh admissions. At the close of the year the patients in the asylum were reduced to 154, 11 of the total number having been discharged, and 8 having died. The daily average sick was considerably in excess of the previous year, rising from 8 to 10, and the number of deaths rose from 5 or 41·9, per 1,000 of average strength to 8, or 56·0. The causes of insanity were unknown in 109 of the total cases under treatment.

Madras.

At the commencement of 1902 there were 568 patients under treatment in the three lunatic asylums (Madras, Vizagapatam, and Calicut) of the Madras Presidency. During the year 168 fresh cases were admitted, bringing the total population up to 736, or 22 more than the number in the preceding year. In the course of 1902 there were 117 cases of discharge, and of these 87 were cured or improved. The accommodation was ample, and there was no overcrowding in any of the asylums during the year. There was less sickness among the patients than in the previous year. The daily average sick fell from

61 to 48 and the deaths from 53 or 94·2 per 1,000 of average daily strength, to 45 or 77·6. There was no epidemic in any of the three asylums. The causes of insanity were unknown in 347 of the total 736 lunatics under treatment during the year.

Bombay. The total population of the seven lunatic asylums of the Bombay Presidency was 1,295, including 522 fresh admissions, against 1,069 in 1901. In the course of the year 425 patients were discharged, 86 of them as cured, and 73 died, leaving 797 under treatment at the close of the year. The health of the inmates continued to be satisfactory; the daily average sick fell from 41 to 38, and the death-rate, per 1,000 of average strength, from 100·0 to 90·0. Of the total of 1,295 lunatics, the causes of insanity were unknown in 525 cases.

Medical Schools.

The number of medical schools open in Bengal during 1902–03 was 11, or one more than in the previous year. The Medical College, Calcutta, and four of the medical schools are maintained by Government, the rest are unaided. The college is affiliated to the University, and prepares candidates for its various medical degrees. The four Government medical schools train pupils as Civil Hospital Assistants, and the five unaided schools follow their own standards for private practice.

The students of the Medical College are required to undergo three University examinations during their five years' study, viz., the Preliminary Scientific examination at the end of the second year, the first L.M.S. or the first M.B. examination at the end of the third year, and the second L.M.S. or second M.B. examination at the end of the fifth year. The total strength of the College at the end of the session 1902–03 was 555 (including 14 women), against 595 in the preceding year. As regards the examinations, 247 candidates were successful, or at the rate of 45·3 per cent., as compared with 44·6 per cent. in the previous year. Of the 247 successful candidates, 23 passed the Preliminary Scientific L.M.S. examination, 82 passed the first, and 64 the second L.M.S. examinations; 45 passed the Preliminary Scientific M.B. examination; 18 passed the first and two the second M.B. examinations. In the combined Preliminary Scientific and First L.M.S. examinations there were only three candidates, but none passed; and 11 passed the combined Preliminary Scientific and First M.B. examinations. There was one candidate for Honours in Medicine, who obtained Honours in the subjects of Medicine, Surgery and Midwifery; and one candidate out of three obtained the M.D. degree.

The average number of students attending the four Government Vernacular Medical Schools at Calcutta, Patna, Dacca and Cuttack was 670 (including 33 women). 111 pupils passed the final examination. One female pupil was successful from each of the Temple and the Orissa Medical Schools, while 50 per cent. of the female candidates passed from the Campbell Medical School, Calcutta.

United Provinces of Agra and Oudh. The number of pupils attending the Agra Medical School in 1902–03 was 244 (including 57 women), or two more than in the preceding year. The results of the examinations are reported to have been satisfactory. The pupils are carefully examined at the end of each year's work, and are not promoted to the next higher class unless they pass the annual examination of their class.

Punjab. The average attendance at the Lahore Medical College and School was more by 43 as compared with that of 1901–02, viz., 515 against 472. Of these 211 were in the College and 304 in the Medical School. The Local Government remark: "The greater recognition of the medical profession as offering a career in life is a welcome feature of the year." The results of the year's examinations show that for the Preliminary Scientific Examination 38 out of 54 candidates passed. In the first L.M.S. and M.B. examinations 25 candidates out of 28 passed, against 12 out of 19 in the previous year, and in the second L.M.S. and M.B. examinations 20 out of 39 passed, against 23 out of 50; in all 83 out of 122 or 68·0 per cent. were successful, as compared with 49 out of 96, or 51 per cent. in the previous year. In the final examination for the hospital assistant diploma 60 passed out of 92, which is a considerable improvement when compared with 28 passes out of 64 candidates in the previous year.

The Medical School for Christian women continues to make progress and to do good work at Ludhiana. The object of the institution is "to provide a thorough medical

training, under fully qualified Christian women, for those Christian women and girls who wish to prepare themselves for medical mission work." At the end of 1902 there were 49 students on the rolls, or five more than in the previous year ; of these 20 belonged to the Medical class, six to the Compounders' classes, 15 to the Nurses' classes and eight to the *dais*.

Madras.

The average number of students at the Madras Medical College (including the School Department) during 1902–03 was 566, of whom 29 were women students. Of the 140 students in the College Hospital Assistant Department, 78 candidates appeared for the final examination and 57 passed. For the various examinations in medicine 111 candidates entered and 64 passed, against 40 out of 81 in 1901. For the first, second, and final examinations for the Apothecary grade 65 candidates passed of whom 9 were women.

The only other medical schools at work during the year were the Vizagapatam School and the Tanjore Medical School. At these there were 10 and 13 pupils respectively on their rolls, all of whom were being prepared for the Hospital Assistants' Certificate. From the Tanjore School 9 candidates appeared for the final examination and 5 passed.

Bombay.

The attendance at the Grant Medical College, Bombay, rose from 569 in 1901–02 to 657 (including 46 women) in 1902–03. For the first University examination in medicine 187 candidates presented themselves, of whom 123 passed ; and for the second examination in medicine 81 passed out of 171 candidates. For the final examination for the degree of L.M.S there were 91 candidates, and of these 37 passed, five of whom were women.

The Government Medical Schools at Poona, Ahmedabad, and Hyderabad continued to work satisfactorily. The average number of students on the rolls was 230.

VII.—SANITATION.

Bengal.

In Calcutta the work of improving bustees, or clusters of native huts, was carried on mainly on the same lines as in previous years. Two hundred and twenty-eight huts were demolished during the year, thereby removing some of the most insanitary plague spots in the city. "In any scheme for a general improvement of the health of the city," the chairman of the municipality remarks, "the remodelling of bustees must occupy a foremost place. Over-crowding, want of air space, light and drains, and the absence of proper sanitary conveniences are the prominent faults in existing bustees, and these can be remedied only by wholesale measures. The provision of accommodation for the surplus population must accompany any properly devised scheme for the demolition of insanitary bustees." Progress was made in the extension of the filtered and unfiltered water-supply, and the wastage of sullage, though still considerable, has been greatly reduced. The total length of filtered water mains and services amounted to about $317\frac{1}{3}$ miles, and the total mileage of unfiltered water pipes was $172\frac{1}{4}$ miles, of which 14 miles were laid down during the year. The works in connection with the suburban drainage scheme were being carried out under eleven separate contracts, eight of which have been executed. A surface drainage scheme for the suburbs was in preparation.

The municipalities of the interior of Bengal spent £150,300 or 43·41 per cent. of their income, on sanitary works (original and recurring) during the financial year 1901-02, being an increase of £3,389 on the expenditure of the previous year. The increase was chiefly under conservancy, the expenditure having risen by £5,340. Various sanitary works were also undertaken or completed in towns and rural areas, by municipalities, district boards, the Government, and private individuals, at a total cost of over £70,000.

The Sanitary Board held only one meeting during the year, but continued to advise the Government and local bodies on the important sanitary projects of the year. Among these were schemes for the improvement of the water-supply, the drainage and the conservancy of various localities, but the work actually carried out was not of great importance. The Board also continued the inquiry into the septic tank system of sewage disposal. The system having passed beyond the experimental stage, sanction was given to the Muzaffarpur municipality to construct a septic tank.

United Provinces of Agra and Oudh.

No new sanitary project of any importance was undertaken during 1902 in the United Provinces of Agra and Oudh, but many improvements in various directions were carried out in the municipalities and smaller centres of population, the prevalence of plague having drawn increased attention to the necessity of such measures. Considerable progress was made towards efficiently draining the site and removing sullage water from the inhabited area in the larger centres of population.

Important drainage works were in course of construction at Allahabad, Cawnpore, Lucknow, Benares, Farrukhabad and Aligarh, and "should prove of great utility in improving the public health of the country." At several other places important projects in connection with drainage were either under consideration or actually sanctioned.

The Sanitary Board met five times in the course of the year, when, among other matters, projects and estimates amounting to about £73,000 for improving the sanitary condition of several municipalities in these provinces were considered. The estimates show an increase of 51 per cent. on those of the previous year.

Punjab.

In the Punjab, important works in connection with the water-supply and sanitation of several large towns were under construction in 1902. Chief among these were the Amritsar water-works, which was making good progress; the Simla sewerage extension works and drainage of the bazaars; extension of the Lahore water-works distribution system; water and drainage works at Lyallpur were put in hand and good progress was made with them; and at Ambala city the extra-mural portion of the drainage scheme was commenced, and was well advanced at the end of the year. The Delhi water-works were completed, and the city is now adequately supplied with pure water. The sale of manure by the municipal towns of the province realised £10,378 against £10,030 in the previous year. As regards rural sanitation, attention was given to the improvement of wells and sanitary conditions in villages. In several districts village sanitary note books have been introduced, and the system was to be extended.

The Sanitary Board held seven meetings during the year, at which several important schemes were approved and forwarded to the Local Government for sanction.

North-West Frontier Province.

No large sanitary work was undertaken during the year in the North-West Frontier Province. The water-supply of Peshawar city was maintained and extended, and a number of new surface drains have been constructed in the city and old ones repaired. At Kohat a new pipe line was constructed to bring drinking water from the springs at Bawana to the railway station, and at Bannu a large new well was in process of construction in the city. The work of cleaning and improving wells and tanks was continued throughout the province. So far the issue of village sanitary note books does not appear to have been attended with any success. Out of their total income of £34,478 the municipal towns spent nearly £9,000 on sanitation.

Central Provinces.

In the Central Provinces the most important sanitary works of the year were the increase of the storage capacity of the Ambajhari reservoir, which supplies Nagpur with water, and the completion of the Bhandara water-works. Want of funds made it impossible to carry out any large scheme of drainage in municipal towns, but in Nagpur and Jubbulpore some advance was made in the construction of roadside surface drains, while the improvement of the water supply at Chanda, Warora and Seoni was also undertaken. As regards rural areas, village sites were cleared and cleaned in the ordinary way, but special measures in the way of rural sanitation were deferred to the year 1903, in which a special grant has been allotted for the purpose. The new Central Provinces Village Sanitation Act came into force towards the close of the year, and the preparation of revised rules under it was undertaken.

The Sanitary Board met in thirteen stations during the year, but owing to want of funds the work under their direction was chiefly in connection with the construction and repairing of wells and the cleaning of village sites.

Assam.

No sanitary work of any special importance was undertaken during the year in Assam, nor was there any large provincial scheme under consideration. Useful work was, however, done by local boards in improving the water-supply in rural areas. The system of sanitary inspection books was kept up in certain villages, but in some cases continued neglect was shown with regard to the submission of these books, in others they were reported as useless and of no practical value, while in others they were regularly submitted.

The Sanitary Board held two meetings during the year, notes being exchanged at other times as requisite.

Burma.

The municipalities of Lower Burma spent 49 per cent. of their income, or 14 per cent. more than in the previous year, on sanitary works. The expenditure on water-supply was more than doubled. A substantial addition was made during the year to the water-supply of Rangoon by means of tube wells, and this fresh source of supply has, it is reported, enabled the municipality to discontinue the use of the Royal Lake water, which had repeatedly been condemned as unfit for drinking purposes. The Hlawga water-supply scheme was still in course of construction. Further progress was made in the important work of reclamation in East Rangoon, and several new blocks had been prepared for the use of the poor ejected from insanitary areas then or about to be reclaimed. The Moulmein water-supply scheme was well advanced at the close of the year, and a similar scheme for the town of Akyab was submitted to the Sanitary Board for approval. Steady progress was being made in the surface drainage of the town of Prome. On rural sanitation a sum of £11,563 was expended during the year from district cess funds, and of this amount 29 per cent. were spent on domestic cleansing.

The Sanitary Board met on three occasions during the year, to dispose of projects forwarded to them for opinion and advice. The Board were of opinion that the question of the drainage of Akyab town should take precedence of the water-supply project; and acting on this advice the municipality applied for the services of the Sanitary Engineer to carry out a combined water-supply and drainage scheme.

Madras.

In Madras city a sum of £22,500 was expended on sanitation during the year, and of this amount £8,400 were spent on the new drainage works. The water-supply was extended to certain parts of the city. The quantity supplied in the course of the year was nearly 3 per cent. greater than in the previous year.

As regards sanitation in other towns, the schemes for the water-supply of Cocanada and Vizagapatam, the construction of the Tiger Hill reservoir in Ootacamund and the extension of the water-supply in Trichinopoly were in progress. Water-supply

schemes for Guntur, Dindigul, and Coonoor, were under the consideration of the Madras Government at the close of the year. Rural sanitation consisted chiefly in conservancy measures.

The Sanitary Board carried out a considerable amount of work during the year. Plans and estimates for 123 sanitary works were scrutinised, amongst them being proposed water-supplies at Kodaikanal, Vellore, and Saidapet, and improvement in the water-supplies at Madura, Trichinopoly, and Adoni. Investigations were in progress in several other towns, and a scheme for the drainage of a portion of Madura town was under consideration. On the recommendation of the Board an estimate of £553 was sanctioned for experimental works, in view of ascertaining the most effective method of filtration of sewage, the experiment to be conducted in the vicinity of the Vaccine Institute, Guindy.

Bombay. In Bombay city good progress was made with the various drainage works ; and the acquisition of properties was taken in hand with a view to commence the subsoil and surface drainage of the lower parts of the city. Drainage connections were carried out for 530 houses, and several latrines and urinals were erected in different parts of the town. The various municipal water-works were maintained in a state of efficiency. During the year 405 water connections were made, and 274 were cut off, leaving a total at the end of the year of 20,683. The Tansa and Tulsi lakes were again well replenished by the rainfall.

The expenditure incurred on sanitation by the district municipalities and the Taluka local boards during the year was higher than that of the previous year, but the Sanitary Commissioner says that " real sanitary progress has been at a standstill for some years past." The cause is to be found in the plague epidemic, which shows no signs of abatement. " Very few of the towns in the Presidency," the Government remark, " have escaped severe outbreaks of plague, which have burdened many with heavy debts." No progress was made in the introduction of the Village Sanitation Act owing to the prevalence of famine and plague, which have absorbed the attention of district officers in recent years.

The Sanitary Board considered and tendered advice concerning schemes for improving the water-supply and drainage of various localities.

Berar. The municipalities of Berar spent 40 per cent. of their income on sanitation as compared with 36 per cent. in 1901. No large sanitary work was undertaken owing to want of funds, and in many of the municipal towns active enterprise was to a great extent paralysed by the presence of plague. Little was done in the way of rural sanitation apart from the clearing of village sites and the improvement, where possible, of the well-water supply. The District Sanitary Board met as usual once at each of the six head-quarter stations, to consider the action taken by local bodies on the recommendations of the Sanitary Commissioner, as contained in his inspection notes of past years on towns and villages.

OF

SANITARY AND OTHER REPORTS

FOR

1902.

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER WITH THE GOVERNMENT OF INDIA, FOR 1902.

(*Surgeon-General Sir B. Franklin, K.C.I.E., M.D.*)

Meteorology of the Year.

Summary of the meteorological conditions of the year.—The following report on the meteorology of India has been kindly furnished by the Meteorological Department of the Government of India :—

The first two months of the year 1902 were unusually free from storms. There were no storms of the usual cold weather type, and the few depressions which were developed over Gujarat and thence advanced through the central parts of the country were feeble and exercised little influence on the weather. The principal features of the meteorology of these two months were abnormal dryness of the air, absence of cloud, very scanty rainfall, and a persistent excess of temperature. In March the weather changed and an unusually large number of depressions passed over Northern India. Notwithstanding this, the accompanying precipitation was in many parts of Northern India less than usual. In consequence the mean maximum temperature and the mean minimum temperature were in excess in all parts of India. The month's rainfall was only in excess in South India, the West Coast, the Gangetic Plain, and Chota Nagpur, Bengal, Orissa, the Burma Coast, and the Bay Islands. In all other parts it was in defect, and in the Deccan, East Rajputana, Central India, and Gujarat, there was actually or practically no rain throughout the month.

In the hot weather months of April and May the rainfall was generally more or less excessive over the Upper Sub-Himalayas. the Gangetic Plain, and North-East India, normal over the Burma Coast, and in defect elsewhere. In consequence the mean temperature was generally in defect over North-East India, more particularly in Central and North Bengal, the Gangetic Plain, and the hill and submontane districts of Upper India, and in excess elsewhere. The excess was greatest in Sind, where it was moderate to considerable. The monsoon rains proper set in on the South Konkan Coast on the 7th of June, spread feebly but rapidly inland and gave a series of thundershowers to Berar, the Central Provinces, and Central India between the 8th and 15th. A storm formed over the Arabian Sea on the 9th and 10th, and advancing northwards carried the monsoon rains to Kathiawar and Gujarat between the 12th and 16th, and to Sind between the 15th and 18th. Between the 17th and 29th the monsoon was very feeble over the Arabian Sea, so that the districts influenced by this branch of the current received usually light rainfall. In the Bay of Bengal a storm formed on the 11th and 12th and passed into East Bengal on the 15th bringing monsoon rainfall with it, but between the 21st and 27th the rainfall was light over North-East India. The month's rainfall was generally light except in the Punjab, Sind, East Bengal, and the Surma Valley. In consequence of this deficient rainfall the mean temperature was generally excessive except in parts of North-West and North-East India. The excess was greatest in the Central Provinces. The highest temperature recorded was 125° at Jacobabad on the 5th. In July the rainfall was approximately normal—except in the North-West Frontier districts, the Indus Valley, and North-West Rajputana, where only a quarter of the normal fall was received, and on the West Coast and in Bengal, where the fall was in moderate excess. The mean temperature was in defect both by day and night over the greater part of the United Provinces, North-East India, and Central and Upper Burma, and in excess elsewhere, the greatest excess being reported from the north-west, where it varied between 2° and 9°. In Gujarat and North Bombay the absolute maximum temperatures were in some cases higher than have been previously observed in July. There was a long break in the rains during the first seventeen days of August over North-West and Central India and the Deccan, and the only districts where the month's rainfall was excessive were Upper Burma, the greater part of North-East India, North Bombay, and the central and

eastern districts of Madras. Elsewhere the rainfall was in considerable defect. The mean temperature was higher than usual at practically all the plains stations, and the diurnal range of temperature was greater than usual. The thermometer rose to 116·6° at Jacobabad on the 1st. Five cyclonic storms occurred during the month of September. Hence there was almost daily rain, and the month's rainfall was in excess in practically all parts of the country. Owing to the cloudy rainy weather the day temperature was generally (and on some occasions largely) below the normal, while the night temperature exceeded the average. The diurnal range of temperature was hence low, and the mean temperature was, over the greater part of the country, less than usual. October was also a disturbed month, and the rainfall was heavier than usual over the greater part of the Peninsula and over the Punjab and adjoining parts of the United Provinces. The mean temperature was low over parts of Burma, Assam, the foot of the Himalayas, the Madras Coast, and South India, and was more or less excessive elsewhere. During November and December there was generally more rain than usual over the Peninsula and less than usual over Northern India. Temperature changed rapidly and considerably during this period, but for the whole time the variations from the normal were neither large nor important.

Both the maximum and minimum temperatures on the mean of the year were below the normal over the inland parts of Burma, Assam, Bengal, and Orissa, but were higher than usual elsewhere. The excess was greatest and about 1½° in the Indus Valley, Rajputana, Central India, Gujarat, and the Deccan, while the deficiency was greatest and about 1·0° in Assam.

Pressure on the mean of the year slightly exceeded the normal over Burma, Assam, Bengal, Orissa, the Deccan, and South India, and was in slight defect elsewhere. For the whole year the variation from the normal was + ·016, and both in February and October the variations from the normal were very large.

The relative humidity on the mean of the year was above the normal over South India, but was below in all other divisions. The two first months of the year were marked by excessive dryness almost everywhere.

The cloud amount was generally below the normal during January, March, June, and August, and varied irregularly from the normal in the remaining months. On the mean of the year there was a trifling excess over Bengal, Orissa, the Deccan, and South India, and a deficiency elsewhere.

The rainfall of the whole year was in excess over Assam, Bengal, and Orissa, the West Coast, and South India, but was in defect in all the remaining provinces. On the mean of the whole area the annual rainfall was 0·37″ in defect.

The rainfall was in general excess in September, but was more or less in defect in the other months, more particularly in January, February, June, and November.

European Troops.

Sickness and mortality in 1902.—The health of the European Army of India during 1902 was not quite so good as during the previous year, for though the admission rate, the constantly-sick rate, and the invaliding rate were all slightly lower than in 1901, the death-rate was considerably higher.

Years.	Average Strength.*	Ratio per 1,000 of Strength.				
		Admissions into Hospital.	Constantly Sick.	Deaths.	Invaliding.	Total Loss.
1896–1900... ...	66,974	1,339	86	17·08	33	50
1901	60,838	1,104	67	12·38	39	51
1902	60,540	1,078	66	14·68	37	52
1891–1900... ...	68,224	1,399	87	16·21	29	45

*The quinquennial and decennial ratios are, of course, worked on the total strength of the lustrum and decade respectively.

The chief causes of admission into hospital were venereal disease and ague. These diseases accounted for 26 per cent. and 23 per cent. respectively of the total number of admissions from all causes. The only diseases with increased admission rates as compared with 1901 were venereal disease and enteric fever. The admission rates on account of ague, simple continued fever, influenza, and respiratory diseases were considerably lower than in the previous year.

The chief causes of death were, as in 1901, enteric fever and abscess of the liver; the death-rates of both these diseases being higher than in the previons year. The death-rate on account of respiratory diseases was also increased. On the other hand the mortality from cholera, simple continued fever, and dysentery was diminished. Enteric fever accounted for 29 per cent. of the total number of deaths, and abscess of the liver for 13 per cent.

The chief causes of invaliding were, in order, secondary syphilis, debility, and ague.

Among the troops comprising the Delhi manœuvres and Durbar Force, the chief causes of admission into hospital were ague and venereal disease, ague accounting for 30 per cent. and venereal disease for 21 per cent. of the total number of admissions from all causes. Enteric fever was the chief cause of death among the troops of this force, accounting as it did for 56 per cent. of the total number of deaths.

Commands and Stations.—Bombay was the most unhealthy of the four commands, Bengal coming next, and both being more unhealthy than in 1901. The highest mortality from remittent fever, heatstroke and pneumonia occurred in the Punjab Command, and the highest from small-pox and ague in the Madras Command. Among stations of over 100 strength the highest death-rates were recorded at Barrackpore, Murree, Kakool, Naini Tal, Attock, and Fatehgarh. The death-rates recorded at all these stations except Barrackpore and Naini Tal, were higher than in the previous year. Abscess of the liver was the chief factor in the mortality at Barrackpore and Naini Tal, and enteric fever at Kakool. Among stations of over 1,000 strength the highest death-rates were recorded at Colaba and Kurrachee, enteric fever being the chief cause in the former station and circulatory diseases in the latter. The death-rate at both these stations was more than three times as high as in 1901.

Geographical groups.—The most unhealthy geographical groups in 1902 were Bengal-Orissa, Central India, and Burma Inland. The highest admission rates on account of simple continued fever, rheumatic fever, and venereal diseases were recorded among the troops in the Burma Coast group; the highest on account of ague among those in the Burma Inland group; the highest on account of influenza, cholera, remittent fever, dysentery, abscess of the liver, and congestion and inflammation of the liver among those in the Bengal-Orissa group; the highest on account of enteric fever and pneumonia among those in the Upper Sub-Himalaya group; the highest on account of small-pox among those in the Indus valley group; the highest on account of tubercle of the lungs and respiratory diseases other than pneumonia among those in the Hill Depôts group; the highest on account of diarrhœa and the lowest on account of venereal disease among those in the Hill Stations group; and the lowest on account of ague among those in the Western Coast group.

Influenza.—The admission rate on account of influenza, which had risen to 8·9 per 1,000 in 1901, fell to 1·8 per 1,000 in 1902. The decrease was general throughout the country, but it was most marked in the Madras and Punjab Commands. The admission rate was, however, as in 1901, highest in the Madras Command, that of the Bengal Command coming next. Among the groups, the Bengal-Orissa group (IV) had the highest admission ratio, the Hill Stations group (XII*a*) coming next, and the Southern India group (XI) third. As compared with 1901, group II was the only fresh one affected, and group VII escaped; in both years all the other groups recorded admissions. Twenty-one stations returned cases, as compared with thirty-three stations in 1901. The largest number of cases occurred at Chaubuttia, where a mild epidemic, causing 31 cases with one death, prevailed during March, April and May. This was the only death recorded under the heading of influenza during 1902. At the *post mortem* examination of the case both lungs showed signs of intense congestion with numerous patches of consolidation, and there were also signs of recent pleurisy on both sides.

The fact that influenza frequently escapes recognition not only in mild cases but even in fatal ones has been emphasized by Washbourn and Eyre. In the examination of

the lungs of 12 cases of broncho-pneumonia occurring in children and adults these observers isolated and identified the influenza bacillus in four; and in four of the other cases a bacillus was found morphologically identical with the influenza bacillus and resembling it also in such cultivations as were obtained. Jochmann and Moltrecht also have isolated a bacillus indistinguishable from the bacillus of influenza in 20 out of 22 fatal cases of broncho-pneumonia occurring as a complication of whooping cough in children. This bacillus was identical with that previously isolated by Jochmann and Krause from the sputum of children suffering from uncomplicated whooping cough, and called by them the *Bacillus pertussis*, Eppendorf.

Cholera.—Only three cases of cholera were admitted among the European troops during 1902, as compared with 12 cases admitted in 1901, and 107 cases in 1900. In 1901 and 1902 all the cases were fatal. The man who died from cholera at Fort William was supposed by the medical officer to have contracted the disease by swallowing water while bathing in the Fort swimming bath. In the two cases occurring at Dinapore the origin of the disease could not be traced.

Small-pox.—Both the admission rate and the death-rate on account of small-pox rose very slightly during 1902 as compared with 1901 ; the number of admissions and deaths respectively being 23 and 4 in 1902, as compared with 20 and 3 in 1901. At Meerut there were three admissions with one death ; at Quetta three admissions ; at Lucknow, Meean Meer, Kirkee and Bellary, two admissions each, with two deaths at Bellary. At no other station was there more than one case. The cases at Meerut are stated to have been probably contracted in the bazaar. The man who died at this station had been twice vaccinated, the last time in 1898. At Quetta small-pox was very prevalent in the district from March to May. At Kirkee one man developed small-pox while in hospital for venereal disease.

Ague, remittent fever, simple continued fever, Malta fever.—Intermittent fever caused 23 per cent. of the total admissions during the year 1902 as compared with 27 per cent. during 1901. The admission rate per 1,000 was less than in 1901, but the death-rate was slightly increased. The most malarious of the four commands was, as in the previous year, the Punjab ; but the admission rate in this command was considerably lower than in 1901. In all the commands except Bengal there was a marked decrease in the admission rate as compared with the previous year. As in 1901, the highest admission rate on account of intermittent fever during 1902 was recorded among troops in the Burma Inland group ; but the troops in all the groups had decreased admission rates as compared with 1901, except those in groups IV, V, VII, and IX. The statistics of all the stations in the Burma group except Port Blair showed a marked decrease in the admission rate of intermittent fever as compared with the previous year, and in each of the four commands the statistics of more stations showed a decrease in the admission rate on account of this disease than an increase. Excluding hill stations a decrease in the admission rate of intermittent fever was noted in 1902 in 42 stations and an increase in 28 stations. The stations at which the highest admission rates were recorded were Fort Dufferin, Attock, Fort Lahore, Deesa and Saugor; all of which returned admission rates of over 850 per 1,000 of average annual strength. The admission rates recorded at Fort Dufferin and Fort Lahore were, however, lower than those of the previous year ; at the other three stations they were higher. Some of the stations at which the lowest admission rates on account of intermittent fever were recorded were Mallapuram, Madras, Bareilly, Thayetmyo, Trichinopoly and Calicut. Some stations with a large increase in the admission rate, as compared with 1901, on account of this disease were Attock, Saugor, Deesa, Cawnpore, Rawalpindi, Kurrachee, Nowshera, Peshawar, Agra, Mhow, and Fort William ; and some with a considerable decrease were Meean Meer, Nasirabad, Fort Lahore, Mallapuram, Fort Dufferin, Amritsar, Thayetmyo and Meiktila. In at least 20 of the hill stations a decrease in the admission rate on account of intermittent fever was also observed.

In nearly all stations where a decrease in the admission rate on account of ague occurred in 1902, as compared with 1901, the medical officers attribute the decrease partially or wholly to measures taken to prevent the breeding of *anopheles* mosquitoes by applying kerosene oil to pools and other collections of water. Judging, however, from an examination of the medical officers' reports of these operations against mosquitoes, it would appear that in only a very few stations were they carried out with sufficient thoroughness as to be likely to have affected the prevalence of mosquitoes in any considerable degree ; and it would be unwise to attribute the decrease in the prevalence of intermittent fever among British troops, a decrease which has been noted this year in the majority of stations throughout India and Burma, not only among British troops but also among native troops and prisoners, to such trifling measures as have been carried out. At Attock the principal source of the malaria-carrying mosquito was said to be the fire-tank at one corner of the barrack square, and a recommendation that this should be covered over was being acted upon. At Deesa the prevalence of malaria was ascribed to a heavy rainfall at the end of August which filled many mosquito pools, and the greater incidence of the disease among the men of the Royal Artillery was attributed to the nearness of their syce lines. Precautions against the breeding of *anopheles* mosquitoes

were taken, and prophylactic doses of 15 grains of quinine twice a week were reported to have been beneficial. At Saugor also the increase in malaria was attributed to unusual rainfall in November; the administration of prophylactic doses of quinine did not give good results. At Cawnpore a prophylactic dose of quinine was given daily and was said to have been beneficial, but the dose given is not stated. At Rawalpindi *anopheles* mosquitoes were found all over the barracks, although all drains were kept carefully swept out and kerosene oil freely applied to all pools and drains for some months, the cantonment authorities having given 100 rupees a month to be spent on kerosene oil for this purpose. Quinine was also used as a prophylactic in this station, but evidently not with sufficient care. At Kurrachee the increased admission rate was attributed to unusual rainfall in the latter part of the year, and the admissions in November far exceeded those of any other month. Quinine parades were instituted and the British Infantry battalion was moved to a health camp 10 miles away, a reduction in the prevalence of malaria being soon afterwards observed. At Nowshera, from the middle of May to the 31st of October, kerosene oil was freely applied to all places where stagnant water was likely to collect; but in this station, as in many others, it is not stated whether any larvæ of *anopheles* were ever found, or whether the application of oil had any effect in reducing the prevalence of mosquitoes. At Bellary, Shwebo, and some other stations, on the other hand, the medical officers state that no *anopheles* larvæ could be discovered by careful search, but that kerosene oil was nevertheless used as orders to that effect had been received. The medical officer at Agra was unable to account for the greatly increased prevalence of malaria among the troops, but the disease was said to be more prevalent and severe throughout the whole district than in any previous year. Mosquitoes abounded everywhere, and *anopheles* larvæ were found in small tanks in connection with wells, as late as the middle of November. The stagnant water in the moat was found to be a favourite breeding ground of mosquitoes. At Mhow, which is one of the few stations where a systematic search for *anopheles* mosquitoes appears to have been made, the larvæ were first found in March. In July and the following months numerous *anopheles* larvæ were found in the overflow water of wells, the water of road-side culverts, drains for carrying off lavatory water, a few tanks, tins containing water placed round the hayricks in case of fire, surface drains, ditches and shallow ponds. It was found impossible to deal effectively with the drains, and larvæ were found in them up to the end of the rainy season. Numerous larvæ were found in the *kutcha* drains near the regimental bazaar, and the medical officer says that nothing is easier than for the mosquitoes developed in these drains after biting infected people in the bazaar to find their way into the adjacent barracks." In support of this contention, it was found that men in the barracks near the bazaar suffered much more frequently from malaria than those in the barracks further removed from it. The decrease in the admission rate for malaria at Meean Meer was far greater than at any other cantonment in India. This cantonment had been examined by the Royal Society's Malaria Commissioners in 1901, and operations based on their recommendations were carried out vigorously during 1902. The chief measures undertaken were: (1) an attempt to lessen the number of *anopheles* mosquitoes by dealing with all breeding places by the systematic cleaning of irrigation channels, the filling in of all pools, and the use of kerosene oil; (2) an attempt to lessen the danger of the large sources of infection of *anopheles* mosquitoes found in the presence of native lines and bazaars, by their removal to a distance or by the systematic treatment of all children in such lines with quinine; (3) an attempt to reduce the number of relapses and possibly of new infections by the regular administration of a dose of 10 grains of quinine twice a week to all the European troops. A summary of the operations carried out at this station up to the end of 1903 will be found under General Remarks, page 105.

The admission rate on account of remittent fever was slightly higher than that in 1901. The months of maximum prevalence of the disease among all the European troops in India were August and September, those of intermittent fever being October and November. Like intermittent fever, however, the disease was more prevalent during the year in the Punjab than in any of the other commands. In this command the monthly admission rates were almost equal from April to October. The maximum month of prevalence for troops in the Madras Command was July, that of intermittent fever being September; for troops in the Bombay Command the maximum month was April, that of intermittent fever being October. The highest admission rates were recorded at Fort William, Fort Chingrikhal, and Cherat.

The admission rate on account of simple continued fever was much lower than that of the previous year. The decrease occurred in the statistics of all the commands, but

like that of ague was most marked in the statistics of the Madras Command. As in 1901, the highest admission rate was recorded among the troops in the Bombay Command; but of the groups the Burma Coast group (1) had considerably the highest ratio. The month of maximum prevalence of this disease was June. The most frequent causes assigned for the attacks were excessive heat, exposure to the sun while at work or at musketry practice, and chills. In some stations all cases were so returned of which the cause was obscure and in which the blood did not react to Widal's test. At Bareilly, from which station the largest number of admissions during the year were returned, the majority of cases were kept under observation for enteric fever, but no signs of the latter disease having developed, and no obvious cause for the rise of temperature being observed, they were returned as simple continued fever. At Mhow some of the cases strongly resembled enteric fever and would have been returned as such but for the fact that Widal's test was negative. It is possible that some of these may have been cases of "paratyphoid" fever.

There were eight admissions and one death from Malta fever during 1902 as compared with five admissions and no death during 1901. Three admissions with one death were recorded at Kasauli, two admissions at Kirkee, and one admission each at Meean Meer, Jullundur and Rawalpindi, respectively. No information is given in the reports of the medical transactions of Meean Meer and Rawalpindi as to how the diagnosis of Malta fever was arrived at. In all the other stations the diagnosis appears to have been established by means of the serum test. In the case at Meean Meer the disease manifested itself after an attack of heatstroke. The medical officer at Kasauli states that this was apparently the first occasion on which the disease made its appearance there, and its cause could not be ascertained. The three cases were all of a severe type and one proved fatal. This case was first admitted for enteric fever, and it is said that Malta fever supervened upon this disease. In the case of another death recorded at this station the disease was first returned as Malta fever, on the grounds that the serum reaction was positive for this disease and negative for enteric fever, but after a short time it became evident on other grounds that the disease was, after all, one of enteric fever, and the original diagnosis was changed accordingly. These facts appear to throw some doubt on the value of the serum reaction test for Malta fever. No serious attempt has apparently been made up to the present in India to isolate the *micrococcus melitensis* from any case of Malta fever reported, and the proof of its existence as a disease of this country rests solely on the results of reactions obtained between cultures of the micrococcus and the serum of patients suffering from "fever."

Enteric Fever:—Water, Milk and Butter.—Although other ways by which enteric fever may be contracted and spread have recently received increased attention at the hands of observers, the dissemination of the disease by means of water still holds a most important place. According to Tavel the proof that water is the source of infection in any given epidemic can be arrived at in one of the following ways: (1) through the proof that the water has been contaminated by the dejections of typhoid fever patients; (2) through the proof that in a place which is supplied from two or more different sources, cases of enteric fever only appear in the houses supplied from a particular source; (3) through the direct proof of the presence of the enteric bacillus in the water by its isolation from it. He gives a critical analysis of the reports of epidemics in which the proof that water was the source of the disease was supplied by one or other of these methods, as well as an account of an epidemic in which he was able to isolate the enteric bacillus from the water. Springfield also has compiled statistics showing that a number of epidemics of enteric fever occurring in the industrial districts under his charge were due to direct pollution of the water-supply, and Gärtner has collected statistics which tend to prove that many epidemics of enteric fever must be attributed to polluted spring water. As regards the proof by the isolation of the bacillus of Eberth from a suspected water-supply, all observers are agreed as to the extreme difficulty of finding and correctly identifying the bacillus in water, and it is a matter of some difficulty to separate trustworthy from worthless observations on this subject. Tavel states that during fifteen years of work he has only once succeeded in finding the typhoid bacillus in water, and Busquet is reported to have said that out of 984 bacteriological examinations of water which he had made with the object of searching for the bacillus only five gave positive results. Koch, who, after much experience, has come to the conclusion that the bacillus has only a very short life in water, states that in his recollection he has only once been able to prove the presence of the bacillus in a suspected water, and in that case only because the well from which the sample of water was obtained was being continually contaminated anew

by the stools of typhoid patients. Bonhoff has also given instances of the cases in which he considers the bacillus was correctly identified in the water-supply, and arrives at the conclusion that they are extremely few ; and that much time may be wasted in a hopeless search for the typhoid bacillus in water. Finally Reichenbach in an account of the relation of well water to enteric fever, expresses the opinion that if there is distinct evidence on other grounds that cases of enteric fever have been due to the water of a particular well, it is only a waste of time to look for bacilli in the water ; it is a question not of whether there are or are not enteric bacilli in the water, but of whether the surroundings and condition of the well are such that the bacilli could have got into it or not. As was noted in this report for 1901, and as has since been pointed out by Tavel, Neufeld, Bonhoff, and others, the frequent negative results of examinations of water are due in many cases to the fact that, owing to the comparatively long incubation period of the disease and to the fact that the diagnosis of the first case in an epidemic is often uncertain, by the time a bacteriological examination comes to be made all the typhoid bacilli have long since disappeared from the water. Bonhoff gives it as his opinion that on an average the bacilli are not present in water longer than four weeks after the moment of infection, that is about 14 days after the outbreak of the disease, and Neufeld states that the bacilli cannot remain alive in unsterilized water longer than two to three weeks. On the other hand Tavel has shown that under certain circumstances typhoid bacilli can remain alive and virulent in water for several months, as, for example, when they are present in the comparatively stagnant water at the blind end of a pipe. He considers, however, that such a length of life of the bacillus in water is exceptional, and that it is much more frequently the case in epidemics that the water is constantly being freshly contaminated during rain-storms or by other means. But it appears that the typhoid bacillus can remain alive much longer in the mud and sediment at the bottom of a well or pipe than in the water itself ; and Busquet, and later Bonhoff, have drawn attention to the necessity of examining the sediment as well as the water itself. In all the five positive findings of Busquet mentioned above, the water contained more or less muddy deposit. Some French authors have attempted to explain the frequent negative results of bacteriological examinations of water by saying that the bacillus after long sojourn in water changes its properties—the changes especially referring to its capacity for being agglutinated. Rodet and Lagriffoul for example have pointed out that different races of the same bacillus may behave differently as regards their agglutination properties, and enteric bacilli from the organs or from water may even be altogether refractive to agglutination. They consider that it must now be admitted that the agglutinability of a bacillus is not the infallible specific criterion it was believed to be, but a contingent and variable quality like other properties of microbes. The difficulties of the research of the bacillus of Eberth in water have also been multiplied greatly since the discovery of numerous varieties of bacilli closely resembling the typhoid and colon bacilli, and according to Burnet (who states that Pellegrini has counted no less than 75 varieties of " false-typhoid bacilli " in the water of Pisa), Bienstock, Simpson, and others, no certain method for its isolation from water has yet been discovered. Neufeld in referring to the isolation of the bacillus from fæces says that none of the methods are suitable for the practitioner but that all are suitable for the expert, and that experience and practice are of more importance than the exact method used ; and a similar observation may be made with regard to the isolation of the bacillus from water. Some of the newer methods are those of Chantemesse, Schepilewsky, Altschüler, Hergemann, Schüder and Cambier. The chief difficulty of the research consists in the separation of true typhoid bacilli from the *B. coli communis* and others closely resembling it. Fitz Gerald and Dreyer consider that the neutral-red method as usually employed for the differentiation of *B. typhosus* and *B. coli* is uncertain, because certain species of Eberth's bacillus and of the *B. coli* do not produce any change of colour in the medium, and different samples of neutral-red are reduced unequally. Roth has devised a method of differentiating these bacilli, consisting in the addition of a 1 per cent. solution of caffeine to the medium, which prohibits the growth of coli but not of typhoid bacilli ; and Omelianski a method based upon the principle that certain microbes when cultivated upon gelatine to which phenolphthaleine and formate of soda have been added, decompose the latter and set at liberty carbonate of soda, in the presence of which the phenolphthaleine causes the medium to become of a rose colour. On this medium the coli bacillus grows well, while the typhoid bacillus only grows very slowly, so that after 24 hours the typhoid colonies, not having developed very much, do not cause any change in the colour of the medium, while the coli colonies have changed it to a rose colour. Koch considers that of all the methods for the separation of the typhoid bacillus from others resembling it that of Drigalski and Conradi is the best. Neufeld insists on the fact that in order to be

certain that a bacillus isolated from water is really a true typhoid bacillus it must not only agree in all its morphological, cultural, and chemical characters with a known true typhoid bacillus (controls experiments with which must be made at the same time), but that Pfeiffer's immunity experiments must also be carried out, and the bacillus must be agglutinated by the serum of an immunized animal in high dilution, as is the case with a known true typhoid bacillus. According to him the agglutination test can be free from objection only when a powerful serum, the agglutinating power of which is exactly known, is employed. An agglutination with a low dilution of the serum such as 1 in 100 or under, can never be regarded as conclusive; and still less value is to be attached to agglutination when, as is frequently the case, the experiment is made with the blood of a typhoid fever patient, or of a convalesent from the disease, instead of with the serum of an immunized animal; because the blood of typhoid fever patients and convalescents frequently possesses a considerable power of agglutinating certain kinds of *B. coli*. For this reason the methods of isolating the typhoid bacillus from water described by Simpson and others cannot be regarded as satisfactory. Although true typhoid bacilli are so rarely found in water, it is common in India, as elsewhere, to find bacilli of the *coli* group; and it is an important matter to decide whether such a finding, and especially the finding of *B. coli communis*, should be regarded as indicating fæcal contamination of the water. It is usual to say so, and according to Neufeld if such bacilli are abundant in the water so that they can be found on ordinary planted-out plates, one can with some certainty decide that the water has been contaminated. In other cases, however, where the *B. coli* is contained in only a few isolated specimens of the water, and can be cultivated from it only by special methods, Neufeld considers that most observers would not think it justifiable to draw such a conclusion, since the *B. coli communis* has often been found in water which is quite free from suspicion. Having regard to this fact some workers have advocated that the *pathogenicity* of isolated *B. coli* should be regarded as the best criterion of the purity or otherwise of a drinking water; and they consider that if *B. coli* isolated from water are non-virulent when injected into small animals the water may be considered as free from dangerous pollution. This question has been studied by Savage, who concludes that the pathogenicity of isolated *B. coli* is of no help in determining the harmfulness of the water examined, and that virulence as a property of *B. coli* is a very variable character and one which can be readily lost and with greater difficulty acquired. According to Klein the fact that a microbe, owing to insufficient response to certain tests, can be described only as a "coli-like" microbe is at present of indeterminate value in making a definite diagnosis of sewage or other pollution, and it is only when typical *B. coli communis* are found that a certain diagnosis of excremental pollution can be made. Winslow and Miss Hannewell have made a study of the distribution of the *B. coli* and of Houston's streptococci in polluted and unpolluted waters. Their general conclusions were: (1) micro-organisms which ferment sugar are in general rare in non-polluted waters; (2) the *B. coli* is very rare in non-polluted waters (5 times in 157 specimens of water); (3) the group of streptococci and staphylococci would appear to be intimately associated with a recent pollution by sewage. They were found 3 times in 157 specimens (1 c.c. each) of unpolluted water and 25 times in 50 specimens of polluted water. Jordan has also found that in freshly polluted river water non-chromogenic staphylococci were much more abundant than in the purer waters, and that fluorescent bacteria and a group of non-gas producing non-liquefying bacteria were less abundant in polluted than in purer water. As regards the purification of water Proskauer and Schüder have published a favourable account of the use of ozone in actual practice on a large scale at Wiesbaden; and Vaillard has made a special study of the means of purification of water applicable to troops on the march. He comes to the conclusion that the most practicable and efficient method is by the addition of chemicals to the water, and recommends especially the iodine method.

According to Neufeld, milk is, next to water, by far the most important agent in connection with the epidemiology of typhoid fever, and Schüder gives statistics of 110 epidemics as being caused through milk as compared with 462 through water. Since milk is a good medium for the growth of the typhoid bacillus it is often possible to recognise the cause of the disease much sooner in this than in any other medium. Bruck has made a very complete experimental research on the communication of typhoid fever by means of butter. Most of the previous researches on this subject had not been made under such conditions as would usually be met with in actual practice. Three series of experiments were made by Bruck. In the first, pure typhoid cultures were added to milk, and butter was made from the cream which formed after allowing the milk to stand. Typhoid bacilli were found in the cream and in the butter. In the second series the

vessel containing the milk and the apparatus used for making the butter were rinsed with water to which typhoid bacilli had been added. In the third series some pieces of cloth were contaminated with typhoid dejections and then washed in water which was afterwards used to wash out the vessels and apparatus. In all these series of experiments typhoid bacilli were found in the cream and in the butter, even when only a very small quantity of typhoid material was used for contamination. Bruck also found that after the typhoid bacilli had reached the butter they were capable of remaining alive in it for 27 days.

Enteric fever:—*Soil. Dust, Flies, Clothes.*—That an intimate connection exists between sewage polluted soil, and outbreaks of enteric fever is well known, but, as Neufeld points out, it is not the actual soil itself which is of significance in connection with typhoid infection, for the experiments of Koch and others have shown that typhoid bacilli find no conditions in soil which permit of their increase. On the contrary, as Poore has shown, the soil is effective in bringing about the destruction of pathogenic germs, and according to him enteric fever cannot in any way be considered as a "soil disease" in the proper sense of the term. Koch says that the typhoid bacillus is not capable of a saprophytic existence in the ground; and according to Neufeld the reports of earlier authors, such as that of Fülles, who said that the bacilli could be found in any sample of cultivated land in the neighbourhood of Freiburg, and those of Remlinger and Schneider are wrong, and are the result of confusion of the typhoid bacillus with other similar kinds. Such experiments as those of Rullmann, who found that typhoid bacilli were capable of remaining alive in *sterilized* earth longer than a year, are of little value in this connection because they were not made under natural conditions. It is a different matter however if typhoid bacilli reach the soil in conjunction with some suitable medium such as in the fæces, or inside a corpse, and although even under these circumstances but little increase of the bacilli takes place they can remain alive a long time, and under certain conditions can easily effect a spread of the disease to more distant places. Thus Lösener was able to cultivate the bacilli from a typhoid spleen which had been buried 96 days, and, having regard to the difficulties of isolating and identifying the bacillus, Neufeld considers that under such circumstances typhoid bacilli could remain alive much longer even than this. Koch considers that in damp ground, if the bacilli reach it in conjunction with fæces or other suitable medium, they may perhaps remain alive a fortnight, or even occasionally as long as several months. He says, further, that it is possible they can remain alive throughout one winter on the fields, if they are placed there along with the contents of latrines for example, but not much longer; and sums up his conclusion by saying that though the typhoid bacillus may perhaps be able to remain alive outside the human body (especially in the soil) somewhat longer than the cholera bacillus, still, even in that medium, it dies out in a comparatively short space of time. Neufeld admits that a spread of infection can result occasionally from a contaminated soil by infected particles of fæces being blown in the form of dust and deposited on food, &c., and Pfuhl has observed cases where the infection was produced in this way, and where it was proved that the surface layers of the ground had been contaminated by typhoid excreta. Under the conditions of war, where much pollution of camping grounds usually occurs, this mode of infection has lately come to be regarded as a very important one by many observers. Ormerod considers this to be the way by which infection is usually spread in the west of Queensland, where whirlwinds are frequent, and Firth and Horrocks state that infected dry soil, if blown about as dust, is capable of infecting distant objects after 24 days from the time of dessication. That the typhoid bacillus does not, like the tubercle bacillus, as a rule remain alive in the fine dust of a room in which it may be spread about by gusts of wind or draughts, is shown, according to Neufeld, by the epidemiological facts of the disease as well as by many laboratory experiments. Still, the possibility of a few isolated cases being due to this method must be admitted, and according to Schmidt and Weis the enteric bacillus can survive in the air even after thorough desiccation for several weeks.

The question of the conveyance of typhoid infection by means of flies has been closely studied by Ficker, who has shown that 23 days after they have been fed on typhoid cultures flies can still contaminate the objects on which they rest. The bacilli were found on the head, feet, wings, and in the intestines of the flies. Hamilton, in a study of an epidemic of typhoid fever in Chicago, made an exhaustive enquiry into the part played by the common house fly in the dissemination of the disease. Flies caught in two undrained privies, on the fences of two yards, on the walls of two houses, and in the room of a typhoid patient, were used to inoculate 18 tubes, and from five of these

tubes the typhoid bacillus was isolated. The conclusion arrived at was that when discharges from typhoid patients are left exposed in privies or yards, flies may be an important agent in the dissemination of the typhoid infection. Nash, in a paper on the seasonal incidence of typhoid fever and summer diarrhœa, gives facts in support of the agency of flies in the spread of enteric fever, and states that milk infected by flies is the chief factor at least in the case of summer diarrhœa. Dudfield has also obtained evidence of the spread of enteric infection by means of flies, and Welch and others have drawn attention to the importance of this agency. On the other hand, Turner considered the agency of flies in the spread of enteric fever in the South African war to have been unimportant, and states that the highest proportion of admissions for this disease occurred in midwinter when flies were not troublesome.

The danger of contracting infection from soiled clothing has been brought vividly into prominence by the outbreak of typhoid fever which occurred on the training ship "Cornwall," in the case of which the source of infection was traced to contaminated blankets returned from South Africa. Klein is said to have reported that these blankets contained innumerable typhoid bacilli, and if such was the case, the occurrence throws additional light on the persistence of vitality of the enteric bacillus on fabrics, and on the danger of infection by other means than through water. The researches of Firth and Horrocks on this subject were referred to in this report for 1901. Garvin also has described an epidemic of typhoid fever occurring among the Boer prisoners of war at Ceylon, in which the infective material was shown to have been conveyed from South Africa on the clothes of the prisoners themselves.

Enteric fever.—Direct infection.—That enteric fever is frequently communicated by direct infection from one case to another is now recognised on all sides. Neufeld says it is proved by the fact that where a typhoid patient is treated in his own home under bad hygienic surroundings it often happens that a series of cases, separated from one another by intervals of several weeks, occur among the members of his family: thus showing that it is not a question of a common source of infection but of a communication from case to case. Cases of enteric fever occurring among sick attendants or nurses in hospitals, instances of which were given in this report for 1901, frequently offer good examples of this mode of infection. Koch considers it to be, perhaps, the most important of all methods by which typhoid fever is disseminated. In his successful campaign against the disease at Treves he found that all the cases were to be referred to contact; the infection was always carried directly from one person to another, and no trace of a connection with water was to be found. The cases occurring in a house always formed a series in which the disease first attacked one person, then two or three weeks later another, several weeks later another, and so on. An important discovery was the fact that the disease was spread chiefly by the school children, who were always together for the whole day and who frequently carried infective material on their boots from the latrines into the houses. Musehold has described a military epidemic occurring in the autumn of 1900 in Strasbourg, in which the mode of infection was from person to person, and in the sanitary report of the Prussian States for 1895–1897 a number of examples of this mode of infection are given. In an outbreak of typhoid fever occurring in a town in New South Wales, investigated by Millard, it was shown that, although the original source of infection was traced to contaminated milk, yet after infection from this source had ceased, the disease continued to spread to other inmates of houses in which cases had occurred. Hill is reported to have traced one-seventh of all the cases of typhoid fever occurring in one year in the city of Birmingham to personal infection, and Niven is said to have obtained a very similar result with regard to the cases occurring in Manchester. Horton-Smith has published an account of a small epidemic limited entirely to one family, consisting of the father, mother, three daughters, and two sons. All were attacked and two of the daughters died. The first case was undiagnosed, and no attempt was therefore made at isolation, and no precautions taken to prevent the spread of the disease. The second case was attacked about three weeks after the first, and the third, fourth, and fifth a short time after. The sixth and seventh cases occurred about a fortnight after the fifth. In all the cases the attacks were clearly proved to be due to direct infection from the first case or from other members of the family. Bulstrode, Welch, Garvin, and others have also drawn attention to the dangers of this mode of infection. According to Neufeld cases of direct infection are often the result of infective material being taken up on the fingers of attendants either from the soiled body of the patients, or from the bed, or from the utensils used by him, and thence being conveyed to the mouth either directly or through the medium of articles of food. It is not necessary, therefore, for a person to live in the

same room with a patient to become infected in this way from him. Utensils used by a patient, unless thoroughly disinfected, can also be the means of spreading infection in this way for a long time after they have ceased to be used by the patient, since the researches of Gaffky, Pfuhl, Uffelmann, and others as quoted by Neufeld, have shown that the bacilli can remain alive in the dry condition for several months.

Enteric fever.—The bacillus.—In order to obtain successful results in the search for typhoid bacilli in the blood it is necessary, according to Neufeld, to dilute the sample of blood used in the examination very largely, in order to do away with its bactericidal properties. This principle was first successfully carried out by Castellani and Schottmüller. The former obtained 12 positive results out of 14 cases, and the latter 40 out of 50, and in a second series 58 out of 69. Auerbach and Unger got a positive result in 7 cases out 10, Hewlett in 20 out of 24, and Cole in 11 out of 15. Courmont, who only examined typical and severe cases of the disease, found the bacillus in all the 9 cases he examined, and in 4 of the cases even before the Widal reaction was present. Troussaint has also published a case in which the blood contained the bacillus on the fifth day when the serum reaction was still negative. Courmont and Lesieur in an account of all the cases examined by them, either separately or when working in conjunction, claim to have discovered the bacillus in all of 33 cases in which the blood was examined within the first 20 days of the disease. In 4 cases examined on the 20th day, or later, the result was negative. They draw the following conclusions from their work: (1) in all typical forms of the disease the presence of the bacillus in the blood is constant up to the end of the third week; (2) a positive report can usually be given in 24 or 48 hours, but one must wait up to the fifth day after making the culture before a negative result has any signification; (3) there is no evident relation between the agglutinating power of the blood and the rapidity of growth of the culture; (4) the examination of the blood for the bacillus is a method of special value in cases where Widal's reaction is not positive until late on in the disease. Their results have been confirmed in all essential points by Widal, who, however, was unable to obtain a positive result in five mild cases which he examined. These researches show that classical typhoid fever is essentially a septicæmic disease.

Neufeld says that nearly all recent authors agree that typhoid bacilli appear in the urine in $\frac{1}{4}$ to $\frac{1}{3}$ of all cases. Fuchs found the bacilli in 14 out of 41 cases, Richardson in 21 per cent. of cases examined by him, and Vincent in $\frac{1}{5}$ of his cases. According to Neufeld the bacilli appear in the urine at earliest towards the end of the second week, but in most cases later than this, and most frequently first during convalescence. In Vincent's cases the bacilli appeared first in the urine between the 11th and the 17th days of the disease, and their presence did not appear to bear any relation to the gravity of the case or to the abundance of albuminuria. He confimed the fact of the persistence of bacilli in the urine after recovery, and observed three cases of persistent bacilluria. In one of these cases the disappearance of the bacilli was brought about by washing out the bladder with permanganate of potassium solution, and this fact as well as the fact that none of the cases presented any signs of renal disease, led him to think that the bacilli simply increase in the bladder and do not come through the kidneys. Jacobi gives an account of the literature of the subject and a criticism of previous work. From his own results he concludes that bacilluria appears generally from the 13th to the 16th day of the disease, sometimes earlier, and sometimes only during convalescence. It is most frequently observed when the kidneys are diseased and in conjunction with albuminuria, but he admits that it may occur in the absence of any appreciable renal lesion. According to Neufeld and most other authors the administration of urotropine quickly results in the disappearance of bacilli from the urine. Fuchs, however, in the researches referred to above, found that it only caused a temporary reduction in the number of bacilli, that is, that it had only an inhibitory action, and did not cure the case entirely. Ledingham, in the report of a case of typhoid fever in which renal symptoms predominated throughout (the so-called "nephro-typhoid" class of case of Continental authors), states that the prolonged administration of urotropine seemed in no way to affect the number of micro-organisms present in the urine, and typhoid bacilli were found fairly abundantly in a specimen of urine passed by the patient on the day of his discharge from hospital. Goldschmidt has written about a new urine disinfectant, helmitol, which is a preparation similar to urotropine, but having the advantage over that drug of being more soluble in water.

In his experiments in combating typhoid fever Koch has employed the method of Drigalski and Conradi in preference to all others for isolating the typhoid bacillus from

the fæces. He states that with this method a sure diagnosis can be given in 20–24 hours, and at a much earlier stage of the disease than that at which it is possible to obtain Widal's reaction. In one case which occurred in his laboratory the diagnosis was proved on the second day of the disease. In addition it was possible by this method to isolate typhoid bacilli from the stools of many people who were apparently healthy, but who had come into direct contact with cases of typhoid fever. Chantemesse has shown that in some cases of typhoid fever the bacillus may still be present in the stools for over a month after the cases have been cured, and in this way may be explained the diffusion of infection and the apparently spontaneous occurrence of many cases of typhoid fever.

Jehle isolated typhoid bacilli not only from the hæmorrhagic sputum of cases complicated by pneumonia, but even in cases complicated with simple bronchitis. Similar observations by other workers were quoted in this report for 1901. From a careful survey of the literature corroborated by his own bacteriological investigations Glaser concludes that the part played by the typhoid bacillus in cases of lobar pneumonia occurring in typhoid patients is only of secondary importance, the infecting organism being unquestionably the pneumococcus. Glaser, Jehle, and others have found that the typhoid bacillus may still be present in the sputum some time after convalescence is well established. Glaser points out that if the sputum be not disinfected for a considerable period it may prove a source of infection, and Jehle considers it possible, though not probable, that infection may be contracted by cough-spray. According to Welch there is at present no positive or experimental proof that the origin of the disease can occur through the respiratory tract, and the finding of typhoid bacilli in the sputum is so rare as not to deserve consideration from this point of view.

Some of the opinions of observers on the vitality of the typhoid bacillus in water, soil, air, and other media have been mentioned above. The experiments of Levy and Kayser are of interest as showing that the typhoid bacillus can, under certain circumstances, retain its vitality in fæces for a long time, and as throwing some light on the more important question of the length of life of the bacillus when it reaches the soil in conjunction with that medium. These observers caused the stools of a typhoid fever patient to be deposited without previous disinfection in a cemented cesspit, in which they were allowed to remain during five winter months. At the end of this time the stools were spread as manure on a garden with a clay soil, where they remained 15 days at the winter temperature. By the examination of the manure at the end of this time it was still possible to isolate typhoid bacilli from it. As no stools from healthy persons were placed in the cesspit with the typhoid stools, the experiment cannot be said to have been made under such conditions as would occur in actual practice, and MacConkey has shown that the presence of the typhoid bacillus cannot be demonstrated in crude sewage or sewage effluents after the lapse of 6–17 days. Pfuhl's results with regard to the length of life of the typhoid bacillus in some of the various media experimented with by him were as follow :—In damp garden earth, 88 days ; in dry sand, 28 days; in water, 26 days ; in milk, 11–13 days ; in butter, 24 days ; in Gervais cheese, 24 days ; on dried linen, 97 days. Kurpjuweit has shown that typhoid bacilli placed in sterile olive oil can still retain their vitality after 10 days but not after 14 days. The interesting experiments of Macfadyen communicated to the Royal Society through Professor Dewar showed that the typhoid bacillus when immersed in liquid air (about — 190° C.) for at long as six months showed no impairment of vitality ; the fresh growths obtained were normal in every respect and the functional activities of the organisms were unaffected.

Enteric fever—Paratyphoid fever.—At the present time the opinion appears to be gaining ground that the clinical term enteric fever includes a group of diseases caused by quite distinct, though very similar bacilli, and that the diseases of this group can only be distinguished from each other by bacteriological research. Attention seems to have been drawn to the subject chiefly by the discovery that in certain typical cases of enteric fever the Widal reaction was persistently negative. In 1897 Gwyn studied such a case, but in 1896 Achard and Bensaude had already isolated a bacillus intermediate between the true typhoid bacillus and the *B. coli communis* from cases of fever clinically resembling enteric fever in every respect, to which they gave the name of "paratyphoid" bacillus. Since then similar bacilli have been isolated from cases by many observers in France, America and Germany, and paratyphoid fever has come to be recognised as a distinct and widespread disease. Reviews of the literature of the disease have been published by Pratt, Neufeld, Kayser, and others. C. Fraenkel in commenting on a case investigated by Hume which was diagnosed clinically as enteric fever, but in which a bacillus differing

from that of Eberth was isolated from the stools and from the cystitic urine, remarks that such cases explain those reported as "undoubted enteric with negative Widal." Still it is not justifiable to regard all cases clinically resembling enteric fever in which the Widal reaction is negative as paratyphoid fever, for this reaction sometimes fails in true enteric fever. Hoffmann, for example, divides the cases clinically resembling enteric fever collected by him into three groups. In the first group of 2,464 cases clinically and epidemiologically resembling typhoid fever Widal's reaction failed 158 times; in the second group of 131 cases in which "Eberth-like" bacilli were found the reaction failed 12 times; in the third group of 18 cases in which Eberth's bacillus was found eight of the cases gave a negative reaction. Out of 69 cases of suspected typhoid fever Schottmüller separated five which were due to the paratyphoid bacillus. The bacillus resembles very closely those of the Gärtner group which are known to be the cause of meat poisoning, and Neufeld draws attention to the similarity between former epidemics of disease known to have been due to meat poisoning and cases of disease now attributed to the paratyphoid bacillus. Like the bacilli of the Gärtner group paratyphoid bacilli isolated from different cases do not, according to Neufeld, agree in all respects with one another, and in the researches of Hoffmann referred to above the serum of rabbits immunized by injections of Schottmüller's paratyphoid bacillus, while it agglutinated this bacillus in a dilution of 1-1,800 was without any action on Kayser's paratyphoid bacillus. Schottmüller and Feyfer and Kayser however describe two types of the bacillus, viz., paratyphoid A and paratyphoid B; and Kayser in commenting on the results of Conradi, Drigalski and Jürgens lays stress on the fact that in the diagnosis of cases of suspected typhoid fever the serum reaction test must be carried out not only with the true typhoid bacillus, but also with *both* forms of the paratyphoid bacillus. From the practical point of view a diagnosis of paratyphoid fever is of importance as, according to Kayser, the mortality of the disease is only between 1 and 2 per cent. An account of the pathological anatomy of a case of the disease has been published by Lucksch.

Enteric Fever:—Suppression and Prevention: Inoculation.—Probably the most important contribution to recent literature on typhoid fever is the account by Koch of a successful campaign against the disease in a locality where it had been endemic for some years. In dealing with typhoid fever, as in dealing with malaria and cholera, Koch considers that measures of attack are better than measures of defence, and that if we can attack the typhoid bacillus at its source in man in a way comparable to that in which we can attack the malarial parasite, special precautions with regard to intermediate channels of infection such as water or soil are unnecessary. Koch admits that he was formerly of opinion that the typhoid bacillus was capable of a saprophytic existence outside the human body, retaining its vitality for long periods of time in water and in the soil; but that from longer experience he is compelled to abandon this view, and to regard the typhoid bacillus as an obligatory parasite for man alone. As in a campaign against malaria, therefore, the two conditions necessary to be fulfilled in the fight against typhoid fever are, first to be in a position to discover all cases of the disease easily, and at as early a stage as possible; and secondly to be in a position to destroy the bacillus in these cases. If this is done the further spread of the disease is impossible, and as typhoid bacilli cannot grow or retain their vitality for an indefinite period in water or soil, any of the bacilli that have previously found their way into either of these media must die out within a comparatively short space of time. Just as in an attempt to estimate the prevalence of malaria in a place but little information can be gained from a survey of the number of cases under treatment in the hospitals, so in the locality of Koch's experiment it was found that the lists of certified cases given by the local doctors gave a quite inadequate notion of the true extent of typhoid fever; and just as in the case of malaria it is necessary to examine the blood of the general inhabitants of a district in order to find out the prevalence of the disease there, so in the case of typhoid fever it was found necessary to use bacteriological methods for the discovery of all cases of the disease. The Widal reaction was considered inadequate as it makes its appearance too late in the disease and often fails in mild cases, and after much research into the best bacteriological method for securing prompt diagnosis, Koch adopted the method of Drigalski and Conradi for isolating the typhoid bacillus from the fæces. In the locality where the experiment was made only eight cases of typhoid fever had been notified by the local doctors, but by this method no less than 72 people were proved to be actually suffering from typhoid infection. Of these 72 people, no less than 52 were children, among whom only three cases had been notified. This discovery, which finds its parallel in the now well-known discovery of Koch with regard to malarial infection, shows that in a place where typhoid

fever has been endemic for many years the older generation, owing to previous attacks of the disease, have acquired an immunity to the infection. Every case in which typhoid bacilli were found was immediately isolated, and rigorous disinfection carried out, with the result that after three months, so far as the group of villages in which the experiment was carried out was concerned, typhoid fever was exterminated. In another group of villages under exactly comparable conditions typhoid fever continued to prevail, so that it may be inferred that its disappearance from the locality of the experiment was entirely due to the methods carried out there. From the point of view of prevention rather than of suppression of typhoid fever Bienstock has given an account of the measures carried out in Paris to prevent the spread of the disease, and statistics of the good results obtained; and Reichenbach an account of the arrangements in Göttingen. Captain Cooper, R.A.M.C., has published statistics showing the good effects of sanitation —more especially directed towards preventing the spread of infection by flies—in controlling the extent and virulence of typhoid fever and dysentery at Harrismith in South Africa. Besredka has prepared a vaccine by heating a culture of the typhoid bacillus suspended in physiological salt solution for an hour at 60° C., mixing it with antityphoid serum by which the bacilli are agglutinated, and separating the agglutinated bacilli from the serum by repeated washings with salt solution. The bacilli thus washed are said to exhibit remarkable capacity for conferring immunity on injected animals. The immunity of animals injected with these typhoid bacilli is said to appear in 24 hours, and during the process of immunization the susceptibility of the animal is not increased but rather diminished. The vaccine produces no alarming symptoms and remains active and effective for a long period. Macfayden, by triturating typhoid bacilli at the temperature of liquid air, has obtained a toxic fluid ("typhoid cell-juice") which was found to confer bactericidal and antitoxic properties on the serum of animals injected with it. A Committee appointed by the Royal College of Physicians to report on the practical safety and prophylactic value of antityphoid inoculations arrived at the conclusion that not only is a lessened susceptibility to the disease brought about as a result of the inoculations, but that the case mortality is largely reduced. The Committee also considered that with due care the process of inoculation was devoid of direct danger, but that under special circumstances there may possibly be some temporary increase of susceptibility to infection immediately following inoculation.

Enteric fever.—Opinions of Medical Officers.—It has been noted for several years that the majority of medical officers make little or no attempt te explain the origin of outbreaks of enteric fever occurring in their stations, and the year 1902 is not exceptional in this respect. Nearly 30 medical officers state either that the cause of the occurrence of cases of enteric fever in their station is unknown, or that "the origin could not be traced." Among the more interesting points noted in the medical transactions are the fact that a certain number of cases were contracted on troopships which had been constantly conveying troops, many of whom had recently suffered from enteric fever, to and from South Africa; and the fact that the disease was introduced into some stations by Boer prisoners of war who were brought to India while suffering from the disease. At Colaba the medical officer was certain that three cases were contracted on the troopships "Tagus," "Sicilia," and "Montrose," respectively, and he attributes a small outbreak which subsequently occurred to the introduction of the disease by the first of the above cases. At Madras the medical officer states that the disease was imported into the fort by Boer prisoners of war in March, four cases being admitted into hospital from the transport direct, and a fifth a fortnight later. An increase in the number of cases occurring among troops in the fort followed the admission of these cases. At the Boer camp at Kakool the introduction of the disease from South Africa by the Boer prisoners of war is also given as the reason for the origin of the cases among the troops, and at Wellington most of the cases occurred among men quartered in Kaiti camp as a guard over the Boer prisoners, among whom the disease was very prevalent. As usual, many cases originated elsewhere than in the stations in which they were treated, and the medical officers at nearly all the hill stations state that some of the cases were contracted at halting places or camping grounds on the road up. At Barrackpore, Allahabad Fort, and Mooltan, the medical officers note that in one or more cases the disease must have originated during the journey by rail from other stations. At Lucknow one battery of artillery escaped entirely. Out of the 54 men attacked at this station 19 had been only one year in India and 7 only one month. At Poona the disease was much more prevalent among the 1st King's Shropshire Light Infantry, and 11 lbs. of rancid butter, part of a daily consignment received from Bombay, was found in the dairy of this regiment at the time

the disease was most prevalent. At Quetta half the cases occurred among the men of the Royal Garrison Artillery, especially among the companies in camp, and the medical officer states that the cause during 1902 did not seem to be in Quetta itself. At Bellary all the cases occurred among the men of the East Yorkshire Regiment, which had recently arrived from South Africa. At most stations the disease was not confined to the men in any particular barrack room, but at Colaba, Agra, and Chaubuttia, the occurrence of cases from the same barrack room, closely following one another, was noted. In many cases the probable source was thought to be impure food or drink partaken of in bazaars, and the medical officer at Umballa, in noting the simultaneous prevalence of venereal disease and enteric fever in particular units, suggests the possibility of the latter disease being contracted at the time and place of exposure to the former. At Pachmarhi and at Quetta it is noted that the disease was prevalent among the inhabitants of the bazaar, and at Poona the nearness of the bazaar (100 paces from one of the barracks) is mentioned as a contributory cause. At several stations flies are said to have probably conveyed the infective agent from latrines to food, and the nearness of latrines to kitchens and the carelessness of natives in leaving the gauze doors of kitchens constantly open, are mentioned as contributing to the chance of this. At Jutogh a latrine was situated within 20 feet of the kitchen, and after its removal no more cases occurred. Duststorms are said have been the possible carriers of infective material from the filth trenches at Nasirabad and Rawalpindi. The practice of storing water after it has been boiled in wide-mouthed earthenware chatties where it is liable to contamination from dust, from the men's hands, or from animals is mentioned by several medical officers as a probable cause of many cases; and at Kirkee, where this practice obtains, B. coli was isolated from the previously boiled water. At several stations it is stated that cases were produced by drinking infected water from irrigation canals while the men were on manœuvres or in camp. The water supplies of Madras, Mhow, Kamptee, Wellington, Mandalay, Ahmednagar, Meiktila, and Umballa are specially mentioned, among others, as liable to contamination. In most stations, however, the water is boiled and treated with permanganate of potassium. Great care is apparently taken in the preparation of aërated waters and Pasteur filters are in use at many stations. At Ahmednagar, however, it is reported that the water is first boiled and permanganated, and afterwards passed through the Pasteur-Chamberland filter—a proceeding which might with advantage be reversed. Two cases at Agra were attributed to men drinking lemonade purchased in the bazaar. Milk purchased from hawkers or in bazaars was suspected as the source of cases in several stations, and although increasing attention seems to have been directed to the subject of dairy management, in a good many stations much remains to be done. The dairy building at Poona was reported to be in every way unsuitable, and the cattle lines were very foul from prolonged use. At Ahmednagar it is stated that although all the milk is boiled, the contractor, in order to save trouble, is allowed to take it to his own house in the bazaar to boil. At Lucknow there was a difficulty in getting milk from the Government dairy farm owing to many of the cows having been sent away temporarily, and in consequence milk was often purchased from bazaar hawkers. The great decrease in the prevalence of enteric fever at Agra is attributed to the improvement in the municipal waterworks, to the stream of the Jumna having been regulated and made to flow at a distance from villages which formerly were a source of pollution, and to the establishment of a Government dairy farm in 1899. At Bareilly the dhobi's washing ghat was moved to a site higher up the river, the water was boiled, and one of the regiments was moved into camp; but the medical officer is unable to say which of these measures, if any, caused the cessation of the epidemic. The decrease at Secunderabad was attributed to the small number of young soldiers, but the Middlesex Regiment, which had most young soldiers, suffered least, perhaps because they employ no native cooks and because milk is not allowed to be hawked about for sale in the lines. The fact that no cases were returned as enteric fever unless they gave the Widal reaction is assigned as a reason for the decrease in the number of cases at Mhow and some other stations. At Mhow, although for this reason the number of admissions was about half that of the previous year, the death-rate was nearly double, and the medical officer considers that in 1901 a number of cases were wrongly diagnosed as enteric fever, the small percentage of deaths and the monthly distribution pointing to this. At least 22 stations were without any case of enteric fever, and Lebong has been immune from enteric fever, locally contracted, for four years in succession. Nowgong has also been free, except for imported cases, for two years. In at least five stations patients developed enteric fever while in hospital under treatment for syphilis. In a fatal case of enteric fever at Jhansi tubercular cavities were found in both

lungs post mortem. A case returned as simple continued fever at Mhow convalesced after eight days' fever, but after twelve days' normal temperature he had a recurrence of fever and died four days later. At the post mortem examination typical ulceration and enlargement of Peyer's patches was found. At Quetta a man who was admitted for tapeworms suddenly became collapsed after passing a large number of the worms, and died four days after admission. At the post mortem examination typical enteric lesions were found in the small intestine.

Enteric fever in 1902.—There was an increase in the admission rate on account of enteric fever during 1902 as compared both with 1901 and 1900. With the exception of these two years, however, the admission rate is the lowest recorded since 1888. The death-rate in 1902 was also higher than in 1901, but slightly lower than in 1900. There were 1,012 admissions and 260 deaths from this disease during 1902, as compared with 776 admissions and 202 deaths in 1901. The average duration of a case during 1902 was about 55 days, and the average number constantly sick 151·41, so that the total annual loss of service due to sickness from enteric fever alone amounted to about 55,264 days.

Enteric fever in the geographical groups.—The highest admission rates during 1902 were recorded among the troops in groups VI, XII*a*, V, XII*b*, IX, and VIII, and from these groups except group VIII higher admission rates were returned than from the same groups in 1901. The admission rates returned from all the groups except group XII*b* were, however, lower than their decennial means. Eight stations of group VI and seven of group XII*a* returned admission rates of over 20 per 1,000.

Enteric fever in stations.—Among the stations at which the average annual strength was over 100, those at which the highest admission rates during 1902 were recorded were Kakool, Kirkee, Nasirabad, and Umballa; and those at which the highest death-rates were recorded were Kakool, Attock, Nasirabad, Roorkee, and Jubbulpore. Twenty-nine stations returned admission rates of over 20 per 1,000, as compared with 15 under the same heading during 1901. Of these stations Shahjahanpur, Bareilly, Roorkee, Meerut, Umballa, Fort Lahore, Sialkot, and Attock were in group VI; and Ranikhet, Bhim Tal, Chaubuttia, Lower Topa, Kakool, Cherat, and Quetta were in group XII*a*.

Relation of enteric fever to age and length of residence in India.—In 1902, as in 1901, the greatest liability to suffer and die from enteric fever was between the ages of 20 and 25, and during the first year of Indian service. In 1901 the incidence of the disease had been less than in 1900 at all age periods except the last, and in all service periods except the first; but in 1902 it was greater at all age periods except the first and the fourth, and in all service periods except the third and the fifth. In 1902 the liability of men under one year's service to fall sick from enteric fever was at least twice as great as in any other period of service.

Plague and some other general diseases—Dengue.—Among the whole European army in India during 1902 there were recorded only four admissions on account of plague, with one death, as compared with two admissions and one death recorded during 1901. Three admissions with one death were returned at Umballa and one admission at Belgam. No officers, women, or children were attacked during 1902. A single case of cerebrospinal fever, which recovered, occurred at Indore. The widespread prevalence of this disease among natives is mentioned in subsequent sections of this report. There were 76 admissions on account of measles, the largest number being recorded at Rawalpindi. Relapsing fever caused one admission at Poona. Out of the 39 admissions returned as beri-beri, 35, with two deaths, were recorded in Burma. Rangoon returned nine admissions with one death. Thayetmyo six admissions, Mandalay nine admissions, and Shwebo eleven admissions with one death. Four of the men admitted for this disease at Rangoon were sergeants, three of them belonging to the same regiment. All the men admitted were said to be free drinkers. In all the cases at Thayetmyo except one the symptoms were those of peripheral neuritis. The medical officer at Shwebo says that none of the cases were contracted locally. All the men who suffered were beer drinkers. Eleven samples of beer were sent for examination but no arsenic was found in any. There were 298 cases of dengue as compared with no case during the previous year. All except three of these cases occurred in the Madras Command, Thayetmyo returning 123

cases, Rangoon 84, and Mandalay 36. The epidemic at Rangoon lasted from March to the end of July, and the disease was thought to have been imported from Hong Kong by the Chinese. At Thayetmyo the epidemic prevailed from May to September, and at Mandalay during July and August. The disease in all stations was highly contagious, but mild in character and caused no deaths. Captain Pridmore, Indian Medical Service, has published an account of the disease as it appeared in Burma, in which he states that the Burma epidemic probably had its origin in a similar epidemic at Hong Kong previously described by Stedman, and that the spread of the disease in Burma followed the important trade route. Graham has attempted to show that dengue is communicated from the sick to the healthy through the agency of mosquitoes (*C. fatigans*).

Tubercle of the lungs.—The admission rate on account of tubercle of the lungs was the same during 1902 as during 1901, but the death-rate was slightly higher. For the quinquennium the mortality of the European troops as well as of the native, from tubercle of the lungs was highest in the Bengal Command. During 1902, however, the highest mortality among European troops from this cause was recorded in the Bombay Command. The death-rates of European troops, of native troops, and of prisoners during the year 1902 were in the proportions of 10, 14, and 75.

Pneumonia and other respiratory diseases.—The admission and death-rates on account of pneumonia were higher than in 1901, both being also higher than the decennial ratios. The troops in the Upper Sub-Himalaya Group (VI) had the highest admission rate for this disease. The months of maximum prevalence were January and February, and the months of least prevalence June, July and August. Among stations the highest admission rate was recorded at Campbellpur and the highest death-rate at Landour.

With the exception of those in the Hill Convalescent Depôts, the troops in the Bengal-Orissa group had the highest admission rate on account of other respiratory diseases during 1902. The stations with the highest admission rates were Sitabaldi, Pallavaram, Poonamallee, Muttra, Dagshai and Barrackpore. In all the above stations the admission rate was over 60 per 1,000.

Dysentery and diarrhœa.—Both the admission rate and the death-rate on account of dysentery were lower than those of 1901. The disease was as usual, most prevalent among troops in the Bengal-Orissa group, and also as regards the commands it was more prevalent and fatal among troops in the Bengal Command. The month of maximum prevalence of the disease as regards all the European troops in India and as regards the troops in the Bengal and Bombay Commands was August, but for the troops in the Punjab Command the maximum month was May, and for those in the Madras Command, June. The highest admission and death-rates were recorded at Barrackpore, (236·2 and 11·66 per 1,000 respectively) ; the next highest admission rate being recorded at Poonamallee (98·6 per 1,000). The medical officer at Barrackpore states that he cannot explain how it is that the men suffer to such an extent from dysentery while officers and civilians are immune. He attributes the men's liability to the disease chiefly to their careless habits, such as omitting to put on warm clothing after sunset or after taking violent exercise, excessive drinking, &c. He regards the disease as contagious, and gives the following instance. While nursing a women whose husband had dysentery a soldier's wife contracted the disease ; after she returned to her own quarters her husband and two children were attacked.

The admission rate on account of diarrhœa was lower than in 1901, but the death-rate was slightly higher. The admission rates among troops in the different groups varied between 23·4 per 1,000 in the Hill Stations group and 3·1 in the Western Coast group. Among stations the highest ratios were recorded at Chaubuttia, Sitabaldi, Lebong and Dagshai.

Hepatic abscess.—Both the admission and the death-rate on account of abscess of the liver were higher than in the previous year, the highest admission and death-rates being returned from the Bengal Command and the Bengal-Orissa group. Among stations, Barrackpore and Naini Tal returned the highest admission and death-rates from this cause. At Barrackpore there were 18 admissions with 10 deaths during 1902, as compared with 11 admissions with 5 deaths during 1901. Of the 18 cases, nine were attributed to dysentery and seven out of the nine died. For the remaining nine cases, of which three died, no cause could be assigned. The medical officer states that most of the men who died from abscess of the liver were said to be heavy drinkers. The type of

dysentery prevailing at Barrackpore is said to be the "amœbic." Of the six cases at Naini Tal, five were associated with dysentery. At the post mortem examination of one of the fatal cases tubercular cavities were found in the apices of both lungs. Other stations with moderately high admission and death-rates from abscess of the liver were Dum Dum, Fategarh, Lebong, Darjeeling, Landour, Murree and Deolali. At Subathu a fatal case occurred in a man convalescent from enteric fever. At the post mortem examination multiple abscesses were found. At several stations cases were, as usual, returned and treated for some time as cases of remittent fever, tubercle of the lungs, or some other disease, and in a few instances the true disease was only discovered at the post mortem examination. According to Vaillard and Dopter it is essentially the amœbic form of dysentery which is associated with abscess of the liver, the bacillary form never giving rise to this disease. Captain L. Rogers, Indian Medical Service, has also published further researches tending to show that the large tropical abscess is almost invariably associated with the amœbic form of dysentery. He considers that this form of dysentery has naked eye and microscopical characters which enable it to be easily distinguished from the more common bacillary type of the disease. Ranzi has reported a case of liver abscess due to Friedländer's bacillus, and Arnott a case of liver abscess in a child aged $2\frac{1}{2}$ years.

Alcoholism.—There were 11 deaths from alcoholism during 1902, giving a ratio of ·18 per 1,000 of strength, both figures being the same as in the previous year. The yearly average number of deaths in the decennium 1891–1900 was seven ; so that the figures of the last two years have been above the average.

Venereal diseases.—Among all the European troops in India during 1902 the total admission rate on account of venereal diseases was 281·4 per 1,000, as compared with 276·0 per 1,000 for the previous year, and 298·1 per 1,000 for 1900. In other words, among every 1,000 men in India during 1902 there were five more admissions to hospital for venereal disease than among the same number of men in 1901. The steady yearly decrease in the admission rate for venereal diseases, which commenced with the year 1896, has therefore been interrupted by a slight increase in 1902. From the reports of medical officers it appears that this increase is to be attributed chiefly to the arrival of a number of regiments, or drafts of regiments, from field service in South Africa. Some of these regiments and drafts brought the disease with them, and in addition it is mentioned by some medical officers that the hope that men recently returned from field service would be well provided with money, attracted more women from surrounding villages into the stations. Other causes were believed to be : the large number of cases contracted in regiments while marching between stations en route to Delhi and to the hills ; the recent arrival of regiments at stations ; the absence of cantonment hospitals in some stations ; and the fact that in several stations diseased women refused to attend at the cantonment hospital for treatment.

Heatstroke.—The death-rate from heatstroke was higher than in the previous year, all the commands sharing in the increase. The highest increase occurred in the death-rate of troops in the Punjab Command. Nowgong, Attock, Meean Meer, and Lower Topa returned the highest admission ratios, and Meean Meer, Rawalpindi, Mooltan, and Kamptee the largest number of admissions. Lower Topa, Fort Lahore, and Kamptee recorded the highest death-rates, and Rawalpindi, Kamptee, and Agra the largest number of deaths.

Invaliding.—In the whole European army of India 2,255 men were invalided during 1902 (37·25 per 1,000 of strength) as compared with 2,393 (39·33 per 1,000) during the previous year. The proportion of invalids to strength was lowest in the Punjab and highest in Bombay. There was a reduction of invaliding ratios in all the commands except Bombay. The percentage of men invalided while under 25 years of age to the whole number invalided was 35 as compared with 42 in 1901, and of those under 30 years of age 83 as compared with 88. Of the total number of men invalided 17 per cent. (as compared with 14 per cent. in 1901) were of less than two years' service, and 48 per cent. (as compared with 60 per cent. in 1901) were of less than five years' service.

Officers.—The chief cause of admission among officers was ague ; and while the admission rates on account of enteric fever, pneumonia, dysentery, and ague rose, those on account of simple continued fever, hepatic affections, venereal diseases, influenza, remittent fever, and respiratory diseases other than pneumonia, fell. The chief cause of death was enteric

fever, and the rate was higher than in 1901. The death-rate from dysentery was also increased. The admission ratios on account of diarrhœa, fevers except ague, influenza, hepatic affections, dysentery, and small-pox were higher than among the men, as were also the death-rates from fevers, dysentery, and circulatory diseases. In the great majority of stations nothing is said by medical officers as to the causation of enteric fever cases occurring among officers, and in most of the remainder the medical officers state that the origin could not be traced. In the case of the officer who died at Jullundur the blood was twice tested for Widal's reaction with a negative result, though in all the cases occurring among the men a positive reaction had been obtained. One of the cases at Kasauli was first diagnosed by the serum test as Malta fever.

Women.—The health of the women was not so good as in 1901. The chief causes of admission into hospital were debility, ague, and the diseases peculiar to women. Debility caused 40 per cent. of the total admissions, and ague 18 per cent. The chief causes of death among women were child-birth and abortion which caused 24 per cent., and enteric fever and remittent fever which each caused 13 per cent. of the total deaths.

Children.—The health of the children also was not so good as in 1901. The chief causes of admission were ague, respiratory diseases, and measles. Among diseases with increased ratios were measles, eye diseases, ague, dysentery, simple continued fever, and tubercular diseases. Ague caused about 22 per cent. and respiratory diseases 11 per cent. of the total admissions. The chief cause of death was diarrhœa. The death-rates of all the diseases in the table showing causes of death, except teething, dysentery, cholera, and small-pox were increased as compared with 1901. Diarrhœa caused about 20 per cent. of the total deaths, and anæmia, debility, and immaturity at birth 16 per cent. Out of the 200 admissions for measles the highest number, viz. 61, was recorded at Rawalpindi. Wellington returned the highest number of admissions from chicken-pox, and Rangoon the highest number from dengue. Two out of the five children who died from tubercle were below 18 months of age, and three were between two and five years.

The liability to death was greatest under six months, the high death-rate for this period being, as usual, to a considerable degree due to cases of immaturity at birth.

Native Troops.

Sickness and mortality in 1902.—The health of the Native troops during 1902 was, on the whole, better than during 1901, though there was a slight increase in the total death-rate.

Year.	Average strength.*	Ratio per 1,000 of Strength.		
		Admissions into hospital.	Constantly sick.	Mortality, including absent deaths.
1896–1900	127,223	781	30	15·69
1901...	122,866	829	30	13·89
1902...	124,231	718	27	15·01
1891–1900	127,666	852	32	16·62

* The quinquennial and decennial ratios are, of course, worked on the total strength of the five-year and ten-year periods respectively.

The chief causes of admission were ague, dysentery, venereal diseases, and non-pneumonic respiratory diseases. The admission ratios on account of small-pox, enteric fever, simple continued fever, tubercle of the lungs, pneumonia, dysentery, and

hepatitis were higher than in the previous year, and those of influenza, cholera, ague, remittent fever, respiratory diseases other than pneumonia, diarrhœa, scurvy, and venereal disease lower. Ague accounted for 38 per cent. of the total number of admissions from all causes. The chief causes of death were pneumonia and remittent fever. Among the diseases with increased death-rates as compared with 1901 were pneumonia and circulatory diseases, but the death-rates from cholera, small-pox, enteric fever, ague, remittent fever, and tubercle of the lungs were reduced. Pneumonia accounted for over 33 per cent. of the total number of deaths, and intermittent and remittent fevers for over 18 per cent. The total number invalided for discharge during 1902 was 1,430, as compared with 1,566 during 1901, the chief causes of invaliding being, as usual, debility, ague, venereal disease, and rheumatism.

The health of the China Garrison was better than in the previous year, that of the Somaliland Expeditionary Force was fair, and that of the Indian Coronation Contingent to England was good.

The native troops, as usual, suffered less from enteric fever, simple continued fever, diarrhœa, hepatic affections, and venereal diseases, and more from each of the other causes of admission given than European troops. The native troops also suffered more from scurvy.

Commands.—As in 1901 and in 1900 the troops in the Bombay Command were the most unhealthy during 1902. Of the troops in the four commands, those in the Bombay Command had the highest death-rates from ague, bowel complaints, hepatitis, and debility; those in the Punjab Command from enteric fever, remittent fever, tubercle of the lungs, and respiratory diseases; those in the Madras Command from cholera, small-pox, simple continued fever, and circulatory diseases.

Geographical groups.—Of the troops in the different groups (*see* Table on next page), those in the Assam group were the most unhealthy during the decennium 1891–1900, but during 1902 those in the Southern India group. The troops in the Burma Coast group during 1902 had the highest admission-rate from simple continued fever and the lowest from diarrhœa; those in the Burma Inland group the highest from non-pneumonic respiratory diseases and the lowest from remittent fever, pneumonia, and scurvy; those in the Assam group the highest from dysentery, diarrhœa, and cholera and the lowest from respiratory diseases other than pneumonia; those in the Bengal-Orissa group the lowest from small-pox and tubercle of the lungs; those in the Gangetic Plain group the lowest from ague; those in the Upper Sub-Himalaya group the lowest from cholera, influenza, and simple continued fever; those in the Indus Valley group the highest from pneumonia, remittent fever, and influenza, and the lowest from venereal diseases; those in the Central India group the highest from ague; those in the Western Coast group the highest from hepatitis; those in the Southern India group the highest from small-pox and cholera and the lowest from enteric fever and dysentery; those in the Hills group the highest from tubercle of the lungs.

Stations, regiments.—Among the large stations in India with an average annual strength of not less than 1,000, the highest death-rates recorded were in 1902 in Bangalore, chiefly on account of pneumonia and ague; Dera Ismail Khan, chiefly on account of pneumonia and ague; Aurangabad, chiefly on account of pneumonia, ague, and remittent fever; and Meean Meer, chiefly on account of pneumonia and remittent fever. Among the regiments the most unhealthy were the 28th Punjab Infantry at Waziristan and Delhi, the 17th Rajputs at Wana, the 4th Madras Infantry at Bangalore, the 23rd Pioneers in Waziristan and Meean Meer, the 38th Dogras in the Tochi Valley and Ferozepore, and the 3rd Madras Lancers at Bangalore. All these regiments suffered especially from ague, the 17th Rajputs suffered in addition from dysentery and the 28th Punjab Infantry from bronchitis.

* *See* footnote to Table on p. 58.

Influenza.—The admission ratio on account of influenza among native troops, as among European troops, was much lower during 1902 than during 1901. The month of maximum prevalence of the disease in 1902, as in 1901, was February. The largest numbers of admissions were recorded among the troops on the Mahsud Blockade and among the troops at Kohat, Bakloh, and Dharmsala. The native troops suffered slightly more than the European troops, but much less than the prisoners.

Cholera.—There were 26 cases of cholera with 15 deaths during 1902, as compared with 35 cases with 19 deaths during 1901, and the admission and death-rates were much below the decennial rates. The month of maximum prevalence of the disease was February, but, as in 1901, cases occurred during eight months of the year. The most important outbreak was that of eight cases at Trichinopoly, all of which occurred among the men of the 1st Moplah Rifles. Six cases with three deaths occurred among the men of the 8th Bombay Infantry at Dinapore. All the men attacked contracted the disease outside the station while visiting the Sonepore fair. Two cases occurred among the men of the 21st Punjab Infantry at Tientsin, in which city the disease was very prevalent. Nothing is said by the medical officers regarding the cases occurring in other regiments.

Small-pox.—There were 75 admissions on account of small-pox with two deaths, as compared with 55 admissions with four deaths in the previous year, and the admission ratio during 1902 was above that for the decennium. The largest numbers of admissions were seven at Dera Ismail Khan, six at Bangalore, five at Baroda, and five at Secunderabad. The largest number of cases occurring in one regiment was five in the 9th Bombay Infantry at Baroda. All these five cases occurred among a batch of recruits who had newly joined the regimental depôt, one of whom had no marks of either small-pox or vaccination. Three cases occurred among the men of the 35th Sikhs, one at Nowshera and two at Dera Ismail Khan. All three men bore satisfactory marks of vaccination.

Ague, remittent fever, simple continued fever.—Intermittent fever accounted for over 38 per cent. of the total number of admissions from all causes among the native army; but the admission ratio was lowered as compared with that of 1901 by 83·9 per 1,000. The admission-rates returned from nine of the geographical groups were lower, and from three higher than those of the previous year. The most malarious group during 1902 was the South-East Rajputana and Central India group, though the admission-rate recorded among the native troops in this group was lower than in 1901. The greatest increase in the ague admission-rate occurred among the troops in the Burma Coast group. For all the native troops in India the most malarious month was October, and the least malarious March. Of the stations at which the average annual strength was over 100, those at which the admission-rates on account of ague were over 1,000 per 1,000 were, in order, Keng Tung, Datta Khel, Deesa, Miran Shah, and Ahmedabad. The greatest numbers of admissions were recorded among the men of the 5th Punjab Infantry and the 12th Bombay Infantry. The 5th Punjab Infantry was stationed in the Tochi Valley, where malaria is very prevalent—as a result, in the medical officer's opinion, of the large amount of irrigated rice and maize land in the vicinity. No measures for the destruction of mosquitoes were undertaken; but during the fever season, which lasted from June till the end of November, a prophylactic dose of 3 grains of quinine was issued to the men three times a week. At Deesa, where the 12th Bombay Infantry was stationed, the months of September, October, and November were said to have been extremely malarious in spite of great efforts having been made to limit the breeding of *anopheles* mosquitoes. Scrupulous attention was paid to keeping all drains and water-courses clean and to prevent water lodging in pools. Fire buckets were regularly emptied out and kerosene oil applied to pools and waste water receptacles. The increase in the prevalence of the disease was attributed chiefly to the close proximity of the Banas river—a small stream flowing in a wide sandy bed in which cultivation is carried on. The edge of the stream is luxuriant with grass and weeds, and small pools of water and irrigation channels are numerous in the cultivated patches, providing very favourable breeding grounds of *anopheles* mosquitoes. The prevalence of ague among the men of the 28th Punjab Infantry at Delhi was attributed to the fact that after the monsoon a large number of pools of stagnant water, in which *anopheles* mosquitoes breed freely, form along the banks of the river. A prophylactic dose of 5 grains of quinine was issued every other day to the men from the 1st September to the end of October. Major Melville, R.A.M.C., the Sanitary Officer of the Madras Command, was deputed to enquire into the cause of the excessive prevalence of malaria among the men of the 4th Madras Pioneers at Bangalore. He found *anopheles* mosquitoes breeding in large numbers in a "tank" near one of the barracks, in the small pools of water on the granite rocks, and in other situations in the lines. He recommended that the lines should be vacated for two or three months, and that measures directed against the mosquitoes in the different breeding places should be carried out. The regiment was accordingly moved into

camp on the 22nd of November, but the men having previously suffered so much from malaria little decrease in the number of admissions was noted before the end of the year.

Remittent fever accounted for over 10 per cent. of the total number of deaths among the native army during 1902. The disease was most prevalent in April and least so in November, though there was no month during which the number of admissions was less than 98. The admission and death rates during 1902 were lower than those of the previous year. The disease was most prevalent in the Indus Valley, the Hills, the Assam, and the Upper Sub-Himalaya groups. The greatest numbers of admissions were recorded at Kohat, Edwardesabad, and Dharmsala. Among regiments, those with the highest numbers of admissions for this disease were the 29th Punjab Infantry at Dera Ismail Khan and the 1st Battalion 1st Gurkhas at Dharmsala.

The largest numbers of admissions on account of simple continued fever were returned from among the men of the 2nd Bombay Lancers at Deesa and the 1st Bombay Lancers at Poona. The medical officer of the former regiment says that the large proportion of cases must be attributed chiefly to fatigue and exposure on the march from Deesa to Loralai.

Enteric fever.—The admission-rate on account of enteric fever during 1902 was double that of 1901, but the death-rate was slightly lower. Though both the number of admissions recorded and the admission ratio were slightly higher during 1902 than the average figures for the preceding ten years, the ratios for native troops are, as usual, very unlike those for European troops, as are also the ratios for native prisoners. The statistics do not reflect the opinion, so prominent of late, that enteric fever is quite common among *adult* natives of India. The admission ratio per 1,000 from enteric fever among European troops was 16·7 and the death ratio 4·29. For native troops the corresponding figures were ·4 and ·10, and for prisoners ·6 and ·13. By those who consider that enteric fever is common among natives the small number of cases recorded among native troops and prisoners is usually accounted for on the supposition that enteric fever, when it occurs among these classes of people, is not correctly diagnosed, but is returned under the heading of some other fever, such as ague, remittent fever, or simple continued fever. If this were the case we should expect the death-rates from these other fevers to be high. The death-rates of all the diseases under which cases of enteric fever might possibly be returned may be compared with regard to European troops, native troops, and prisoners, by means of the accompanying table.

——	European troops. Deaths per 1000, 1902.	Native troops. Deaths per 1000, 1902.	Prisoners. Deaths per 1000, 1902.
Enteric fever	4·29	·10	·13
Intermittent fever	·50	·89	1·10
Remittent fever	·20	1·14	·78
Simple continued fever	·00	·03	·01
Total fever mortality	4·99	2·17	2·02

From this it will be seen that taking either native troops or prisoners their mortality *from all fevers* was considerably below that of the European troops *from enteric fever alone.* Indeed we might add up the total fever death-rates of native troops and of prisoners and the result would still be below the death-rate of European troops from enteric fever alone. The conclusion to be drawn from these figures is sufficiently obvious.

In a paper read before the Royal Medical and Chirurgical Society, Captain Rogers, I.M.S., stated that in the course of 18 months he had diagnosed 26 cases of continued fever in natives admitted into the Medical College Hospital, Calcutta, as enteric fever, and recorded his opinion that only two forms of long-continued fever exist in natives of India, viz., typhoid fever and malarial remittent fever—upwards of 80 per cent. of

continued and remittent fevers occurring in natives of India which lasted three weeks or more being typhoid fever. He considered that typhoid fever in natives differed in no noteworthy respect from the same disease occurring in Europeans in this country, except that the cases tended to be more severe and fatal in natives than in Europeans—a conclusion which is not borne out by the statistics referred to above. His methods of research and his conclusions were severely criticised by Manson, Wright, and Low. Lieutenant-Colonel Henderson, I.M.S., and Major Childe, I.M.S., have also described cases occurring in natives of India, and Major Meyer, I.M.S., has published notes of seven cases—two Brahmins, one Parsi, one Mohamedan, two Goanese, and one Bombay East Indian. Lieutenant McCarrison, I.M.S., has written of the disease as it occurs among Gurkhas, and Maxwell has published cases occurring among the natives of Southern China, where, he says, the disease is endemic among the native population. He had, however, never met with a serious epidemic of the disease, and never with a case in a child under 12 years of age. The spread of the disease from person to person appeared to take place chiefly, if not entirely, by direct infection. Kennard has recorded his opinion that typhoid fever is rare among the natives of British Guiana.

Among the whole native army of India 50 admissions with 12 deaths were returned during 1902, as compared with 26 admissions with 15 deaths during 1901. Kila Drosh, Abbottabad, Lansdowne, Dharmsala, and Kohat returned the highest numbers of cases. Thirty-one regiments contributed to the total, the largest number of cases in any regiment being eight in the 2nd Battalion 2nd Gurkha Rifles at Kila Drosh. In two of the cases occurring in this regiment the diagnosis was confirmed at a post mortem examination. The medical officer attributes the disease to impure milk drunk on the march. A post mortem examination confirmed the diagnosis in one of the cases occurring in the 1st Battalion 2nd Gurkhas. In this case it was supposed that infection was contracted at Miran Shah, in the Tochi Valley. The medical officer remarks that cases occurring in this regiment are generally imported, or occur in men very recently joined. One of the cases occurring in the 2nd Battalion 39th Garhwal Rifles, at Lansdowne, also was admitted shortly after enlistment, and most probably contracted the disease outside the station. One of the cases occurring in the 2nd Battalion 5th Gurkhas was contracted while on duty in the Boer camp at Kakool, where the disease was very prevalent.

Four cases of Malta fever were returned—two from the 9th Bengal Lancers, and one each from the 4th Rajputs and 40th Pathans. No remarks on these cases are made by the medical officers of the regiments.

Plague. Cerebrospinal fever.—During 1902 there were 192 cases (158 admitted to hospital) of plague with 95 deaths, as compared with 70 cases with 41 deaths during 1901, 56 cases with 29 deaths during 1900, 76 cases with 45 deaths during 1899, and 94 cases with 58 deaths during 1898. The largest number of cases in any station was 81 at Bangalore, occurring in the 4th Madras Pioneers, the 3rd Madras Lancers, the Madras Sappers and Miners, and the 11th Coorg Infantry. The medical officer of the 4th Madras Pioneers says that many of the married men, who were not allowed to keep their families in the lines, kept them in the previously affected localities of the cantonment, and that in this way the disease spread to the lines. Out of the 33 cases occurring in this regiment, 14 had been inoculated: of these 6 recovered, 5 died, and 3 remained under treatment at the end of the year. Of the 19 uninoculated cases, 14 died, 3 recovered, and 2 remained under treatment. The disease was very prevalent amongst the families and followers of the 3rd Madras Lancers at Bangalore, and 24 attacks with 17 deaths occurred among the men. All the men and followers were inoculated and the regiment moved into camp, which checked the spread of the disease at once. Two cases occurred among the inoculated men of the 11th Coorg Infantry, one of which proved fatal.

Cerebrospinal fever decreased from 28 admissions with 21 deaths during 1901, to 18 cases with 17 deaths during 1902. The largest numbers of cases were five among the troops employed on the Mahsud Blockade, and four in the 29th Punjab Infantry at Sarwekai. There were also two each at Miran Shah and Ajmer, and one each at Jullundur, Ferozepore, Myitkyina, Kamptee, and Loralai. The medical officer of the 4th Sikh Infantry says that cerebrospinal fever appears to be always present among the civil population of Miran Shah and the neighbourhood, and from time to time the disease carries off men in the regiments there. Three cases of the disease among the civil population had been observed by him about the time of the occurrence of the regimental cases. Of the cases among the troops employed on the Mahsud Blockade and of those occurring in the other regiments mentioned above, nothing is said by the medical officers.

Tubercle of the lungs.—Although there was a slight rise in the admission ratio on account of tubercle of the lungs as compared with that of the previous year, the death-rate was slightly diminished. The admission-rates recorded among the troops in the Punjab and Madras Commands were higher than those of 1901. Of the geographical groups, the admission ratios returned from the Hills, the Assam, and the Upper Sub-Himalaya groups were much the highest for the year; and of the Commands, Hyderabad and Madras returned the lowest death ratios. Four out of the six highest admission numbers were recorded among Gurkha regiments, and two among Bengal Lancer regiments. The highest number of admissions during the year occurred in the 1st Battalion, 4th Gurkha Rifles, at Bakloh. The medical officer of the regiment records his opinion that Gurkhas have a special hereditary susceptibility to the disease, and considers that the immediate cause is the inhalation by susceptible persons of infected dust from the mud floors of the barrack-rooms. The floor space per man of the barrack-rooms of this regiment is below that prescribed by regulations. The medical officer of the 1st Bengal Lancers at Lucknow attributes the prevalence of the disease to the fact that the regiment spent the previous winter at Hong Kong, and contrasts the somewhat high prevalence of the disease in his regiment with the very low prevalence in the 7th Rajputs, who also wintered in China, but were stationed in the north where the cold was intense but the air dry and bracing. A marked increase in the number of cases of tubercle of the lungs occurred in the 11th Bengal Lancers at Meean Meer. The medical officer considers it to be due entirely to the complete absence of any means of ventilation in the men's quarters. He states that in these quarters there are no outlets or inlets for air except those left by badly fitting doors, and that, owing to some of the syces having to occupy the same rooms as the soldiers, the cubic space per man is very deficient.

Twenty-three admissions with one death were returned as non-tubercular phthisis during 1902, as compared with 13 admissions with three deaths during 1901.

Pneumonia and other respiratory diseases.—During 1901 there was an increase in the prevalence of influenza and a fall in the admission and death ratios from pneumonia. During 1902 these relations were reversed, a considerable decrease in influenza being accompanied by an increase in the admission and death rates from pneumonia. During 1902 pneumonia caused over 33 per cent. of the total number of deaths, and was, as usual, the chief cause of death. The admission ratios were, as usual, highest among the troops in groups VII. and XII., that of the troops in group VI coming next. In these three groups, as well as for India as a whole, pneumonia was most prevalent during the cold months, especially in December, January, and February. Admission ratios over 50 per 1,000 were recorded among the troops stationed at Wana, Mir Ali Khel, Tank, Sibi, Ootacamund, Mercara, and Jullundur; and death ratios over 20 per 1,000 at Wana, Tank, Mir Ali Khel, and Sibi. The largest number of cases occurred among the 17th Rajputs at Wana, the disease appearing in epidemic form during the latter part of the year. The medical officer of the 2nd Sikhs at Kohat attributes the prevalence of pneumonia to the fact that the men leave their quarters insufficiently clad in the early morning to perform their ablutions, a severe chill resulting in some cases. The disease was most prevalent in the 1st Sikh Infantry at Kohat during December, January, and February, and seemed to attack the strong as readily as the weaker men. The 21st Madras Pioneers suffered chiefly while employed on the North-West Frontier, where the cold was severe. The disease was also prevalent and of a severe type in the 43rd Gurkha Rifles at Shillong and the 20th Punjab Infantry at Meean Meer.

Other respiratory diseases were most prevalent in the Bombay Command and in the Burma Inland, Burma Coast, and Western Coast groups. Omitting stations at which the average annual strength was less than 100, Wana was the only station at which an admission-rate of over 100 per 1,000 of strength was recorded. Stations returning death ratios of over 5 per 1,000 were Tank and Kajuri Kach. The 30th Burma Infantry at Bhamo, the 1st Bombay Grenadiers at Aden, and the 28th Bombay Pioneers at Khusalgarh and Quetta, had considerably the highest numbers of admissions; the 27th Rajputs at Wana and the 6th Bombay Cavalry at Fort Sandeman coming next. The medical officer of the 1st Bombay Grenadiers at Aden says that most of the men who suffered from bronchitis had had the disease several times before, and that dust may have been an exciting cause of the attacks.

Dysentery and diarrhœa.—The admission and the death-rate on account of dysentery were higher during 1902 than during 1901. Increased admission-rates were returned from all the groups, except the Gangetic Plain, the Upper Sub-Himalaya, the Western

Coast, and the Southern India groups. Of the 16 stations of over 100 strength at which admission ratios above 100 per 1,000 were recorded, seven were in the Hills, five in the Indus Valley, and one each in the Assam, the Bengal-Orissa, and the Gangetic Plain groups. At Aden also an admission-rate of over 100 per 1,000 was recorded. The highest admission ratios were returned from Aden, Datta Khel, Barrackpore, and Mir Ali Khel; and the highest death ratios from Silchar and Aden. The 1st Bombay Grenadiers at Aden had the largest number of admissions, the 17th Rajputs at Wana coming next. The medical officer of the 1st Bombay Grenadiers says that dysentery cases were due partly to bad food and partly to the fact that owing to the pollution of the ground by the native population, the dust blown about by the wind was contaminated with dried fæces. A large number of cases of dysentery of a mild type occurred among the 16th Rajputs soon after their arrival at Alipore. The food stuffs in the bazaar were found to be of good quality, and it was suggested that, owing to the dearness of fuel, the men did not cook their food properly. After the issue of an order urging the men to thoroughly cook their food, a marked diminution in the number of cases of dysentery and diarrhœa was observed. Dysentery prevailed, as usual, more during the second half of the year than the first, the months of greatest prevalence being July, August, and December.

Though the admission ratio on account of diarrhœa during 1902 was slightly lower than during 1901, the death ratio was twice as high. The disease was most prevalent in the Assam and the Hills groups. Of stations in the Assam group, Manipur returned the highest ratio, and of those in the Hills, Loralai. The ratios recorded at Aden, Peshin, Fort Stedman, Tank, Fort Sandeman, Doranda, Barrackpore, Delhi, and Mir Ali Khel, were, however, all higher than that at Manipur, though lower than that at Loralai. The highest death ratios were recorded at St. Thomas' Mount, Dinapore, Fort Stedman, and Barrackpore. The cases of diarrhœa at Loralai were attributed to a bad water-supply; and towards the end of the year a new supply was installed to check the prevalence of the disease. At Aden bowel-complaints were attributed to chills resulting from insufficient precautions being taken by the men to guard against the cold wind blowing in the evening.

Venereal diseases.—Venereal diseases were nearly nine times as prevalent among European troops during 1902 as among native troops. While among European troops an average annual strength of 60,540 gave 17,036 admissions, in the case of native troops an average annual strength of 124,231 gave only 4,071 admissions. In other words, there were only 33 admissions into hospital for every 1,000 men among native troops, as compared with 281 admissions for every 1,000 men among British troops. Among all the native troops in India the admission-rate during 1902 was 1·5 per 1,000 less than during 1901. There were nine deaths and 121 invalidings directly due to venereal disease. The admission-rates among troops in the Bombay and Madras Commands were the highest for the year; but, as compared with 1901, the admission-rates returned from all the commands except Bengal, as well as the rate among the troops of the Hyderabad Contingent, showed a decrease, the greatest decrease being noted in the admission-rate of the troops of the Hyderabad Contingent.

Beri-beri.—There were in all 84 cases of beri-beri during 1902, 83 having occurred among the Madras regiments, and one in a Bombay regiment, as compared with 108 cases, all among the Madras regiments, during 1901. The 3rd and the 13th Madras Infantry regiments at Singapore had between them the highest number of admissions (34), the 7th Madras Infantry at Vizianagram coming next. Probably on account of the lesser prevalence of the disease during 1902 medical officers have said little or nothing about it in their reports, the only point worthy of note being the fact that in some regiments the disease prevailed chiefly among the recruits.

No advance in our knowledge of the causation of beri-beri that is worthy of record has been made during the year under review. McClosky found that the administration of arsenic to beri-beri patients did not produce any good effects, nor did it aggravate the disease, and concludes for this reason that it cannot be the causative agent. Bertrand, moreover, has shown that arsenic is normally present in all animal tissues, and that the skin, hair, and nails are particularly rich in it.

Jails of India.

Sickness and mortality in 1902.—The year 1902 was hot and rather dry, the rainfall being, however, only very slightly deficient. The monsoon began feebly, but the rainfall over the greater part of the country in July was approximately normal. In August there was a long break in the rains, followed in September by a rainfall in excess of the average in practically all parts of the country. The health of the general population and of the prisoners was good.

The chief causes of admission to hospital were ague, dysentery, abscess, and diarrhœa. The only diseases with raised admission-rates as compared with those of the previous year were tubercle of the lungs and enteric fever. Ague accounted for 41 per cent. of the total number of admissions, and bowel-complaints for 16 per cent. The chief causes of death were dysentery, tubercle of the lungs, and pneumonia. Among the diseases with lowered mortality were dysentery, cholera, and pneumonia. Dysentery and diarrhœa caused 26 per cent. of the total deaths, tubercle of the lungs 17 per cent., and pneumonia 14 per cent.

Administrations.—The health statistics of the prisoners in all administrations except in the Andamans, the North-West Frontier Province and the Central Provinces, were more favourable than those of the previous year. The most unhealthy administrations were, in order, the Andamans, Bengal, Assam, the Punjab, and the North-West Frontier Province; and the three most healthy, in order, Madras, Burma, and Berar. Of the former group the first, fourth, and fifth were more unhealthy than in the quinquennium. As compared both with the previous year and with the quinquennium, the year 1902 had increase of mortality in the Andamans from remittent fever, tubercle of the lungs, pneumonia, other respiratory diseases, and dysentery; in Burma from respiratory diseases other than pneumonia; in Assam from tubercle of the lungs and pneumonia; in the Punjab from tubercle of the lungs, pneumonia, diarrhœa, remittent fever and small-pox; in the North-West Frontier Province from pneumonia, tubercle of the lungs, and dysentery. Thus, four of the provinces just mentioned had increased mortality from tubercle of the lungs and pneumonia, as compared both with the previous year and the quinquennium.

Andamans.—The rainfall of 1902 was heavy, six inches more than in 1901, and 25 inches more than the average of the preceding five years. The unhealthiness which marked the year is stated not to have been confined to the convicts and the police, but to have affected all classes of the community. The free population suffered much from malaria, and it is said that phthisis is increasing among them. Besides the general medical and sanitary report, the senior medical officer submitted separate special reports on malaria, on tubercle of the lungs, and on dysentery, the three scourges of the settlement. He pointed out that sickness and mortality were highest wherever hard work and exposure in the open were most in force. Frequent use was made of the microscope in the diagnosis of malaria and tubercle. The type of malaria in the female jail is said to be more virulent than in previous years, and many of the children harbour malarial parasites. Recently admitted prisoners suffered most from remittent fever. The measures adopted more or less extensively, and believed to have obtained a certain amount of success, were the institution of mosquito brigades, the use of mosquito nets, the prophylactic issue of quinine, and the protection of prisoners from the risk of exposure. With regard to the prevalence of tubercle of the lungs, it was shown that the floor space per prisoner is not sufficient and that four rows of prisoners sleep in a barrack, and that care is not taken to ensure that clothing is dry. It was proposed to facilitate the early detection of cases by frequent inspections and regular weighments, and sanction had been asked for the necessary increase in establishment. A special ward to hold fifty phthisis patients was nearly ready for occupation, but another is needed. As to accommodation, it was proposed to begin with the invalid and convalescent gangs, and obtain for them, by building, a floor space of 50 square feet per man. Arrangements were made, or proposed, to keep clothing dry, to disinfect barracks from which cases came, to boil infected clothing, to watch over the milk supply, and to inform prisoners regarding the nature of the disease and the danger of infection.

The stools of patients suffering from phthisis and dysentery were burned in special incinerators at the various hospitals.

The classes which suffered most from dysentery were the invalids, the prisoners recently admitted, and those employed on hard outdoor labour. Infection was considered to occur directly, through the soil, or by the medium of flies. Since the adoption of

Prisoners.

* The quinquennial and decennial ratios are, of course, worked on the total strength of the five-year and ten-year periods respectively.

† Excluding subsidiary jails.

‡ Including Ajmer, Quetta, and Mercara.

(*a*) Excluding jails transferred to North-West Frontier Province.
